Simple bacterial folliculitis often resolves spontaneously without scarring.[17] When treatment is desired for mild infection, topical antibiotic cleansers such as chlorhexidine, topical antibacterial agents (e.g., mupirocin, clindamycin), and benzoyl peroxide usually are effective.[17,43] In severe or refractory cases, systemic antibiotic therapy (e.g., first-generation cephalosporin, penicillinase-resistant penicillin, clindamycin, tetracycline, fluoroquinolone) is used.[17]

Less common forms of bacterial folliculitis include sycosis barbae, gram-negative folliculitis, and hot tub folliculitis. Sycosis barbae is a severe, recurrent form of facial folliculitis due to *S. aureus*. Painful, erythematous follicular papules and pustules involving the entire depth of the follicle develop on the chin, upper lip, and angle of the jaw, primarily in young black males. Papules can coalesce into plaques, and healing may occur with scarring. Treatment includes warm saline compresses and a topical antibiotic such as mupirocin. Extensive or recalcitrant cases may require therapy with a systemic antistaphylococcal antibiotic with attempted eradication of *S. aureus* carriage.[43]

Gram-negative folliculitis primarily occurs in patients with treatment-resistant acne vulgaris who have received long-term therapy with broad-spectrum systemic antibiotics.[44,45] Prolonged use of antibiotics likely alters normal nasal flora, allowing colonization with gram-negative organisms.[44] However, gram-negative folliculitis also can occur in patients without a history of prolonged antibiotic use.[45] In most patients, lesions consist of perioral and perinasal papules and pustules most often due to *Klebsiella* spp., *Enterobacter* spp., or *Escherichia coli*. A deeper form consisting of inflamed, painful nodules on the face and trunk caused by *Proteus* spp. occurs less commonly. Culture of infected follicles is necessary to establish the diagnosis. Treatment consists of an oral antibiotic selected by susceptibility test results.[44] Isotretinoin is an effective treatment option for severe, recalcitrant cases, but because of the potential for severe side effects, use should be limited to experienced providers.[17]

Hot tub folliculitis is caused by *Pseudomonas aeruginosa*. This infection is seen in patients who bathe in contaminated water or use objects contaminated with *P. aeruginosa,* and it occurs when the bacterium gains entry into the skin through hair follicles or breaks in the skin.[46] Outbreaks of *Pseudomonas* folliculitis have been associated with exposure to underchlorinated swimming pools, whirlpools, hot tubs, and saunas.[46,47] Follicular erythematous macules, papules, and pustules develop in areas of skin exposed to water and abrasive garments (e.g., bathing suits, diving suits). Onset usually occurs 6 to 48 hours after exposure. Fever, malaise, and lymphadenopathy develop occasionally. The eruption usually resolves spontaneously within 1 to 2 weeks,[46,48] often leaving postinflammatory hyperpigmentation.[48]

The diagnosis of hot tub folliculitis is based on history and isolating the organism from culture of purulent lesions. Aa topical agent with antipseudomonal activity (e.g., 0.1% gentamicin cream or ointment) sometimes is used. A systemic antibiotic such as ciprofloxacin is considered for patients with constitutional symptoms.

Pseudomonas hand-foot syndrome, which manifests as painful, red nodules on the palms and/or soles, may be seen in conjunction with hot tub folliculitis or as an isolated infection. The disease course and treatment are similar to those of *Pseudomonas* folliculitis.[46] *Aeromonas hydrophila* folliculitis is an eruption that mimics *Pseudomonas* folliculitis and has been reported in children exposed to contaminated water while swimming.[49]

Malassezia (*Pityrosporum*) folliculitis is a follicular infection caused by the fungus *Malassezia furfur* and is included in the differential diagnosis of infectious folliculitis and truncal acne vulgaris. *Malassezia* folliculitis manifests as pruritic, 2- to 3-mm, monomorphic, erythematous, perifollicular papules and papulopustules on the back, chest, and upper arms.[50–52]

Predisposing factors include diabetes mellitus, malignancy, HIV/AIDS, organ transplantation, and prolonged oral antibiotic therapy.[50,51,53]

The diagnosis of *Malassezia* folliculitis is made by microscopic examination of a potassium hydroxide–treated scraping from a lesion, which reveals budding yeast and spores.[50–52] The skin biopsy also shows dilated follicular ostia with budding yeast and spores, but it rarely is necessary for diagnosis.[50,51,53] Isolation of the organism in culture requires use of a special lipid-containing medium.[51,52]

Mild cases of *Malassezia* folliculitis can be treated with topical imidazoles or selenium sulfide. Systemic antifungal agents (i.e., fluconazole or itraconazole) are indicated for immunosuppressed patients or those with extensive lesions.[50,53] Because recurrence of *Malassezia* folliculitis is common, maintenance regimens of oral or topical antifungal agents often are prescribed after effective treatment.[51,52]

Furuncles and Carbuncles

A furuncle (i.e., boil) is an infection of the hair follicle, but unlike folliculitis in which the infection remains in the epidermis, the inflammation in furuncles extends deep into the dermis.[12,43] Furuncles can originate from a preceding folliculitis and manifest as tender, deep-seated, erythematous, perifollicular nodules with an overlying pustule (Fig. 68.6). With time, the inflammatory mass becomes fluctuant and often opens to the skin surface, draining purulent material.[17] Lesions are found on hair-bearing areas, with the face, neck, axillae, buttocks, and groin commonly affected.

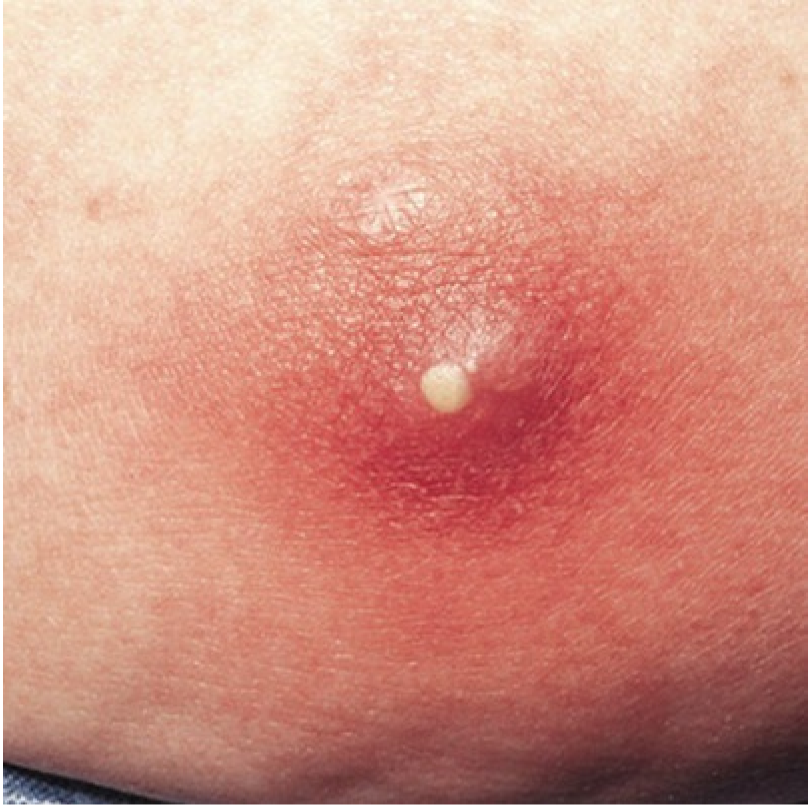

FIGURE 68.6 Furuncle due to *Staphylococcus aureus*.

(Courtesy of J.H. Brien, ©.)

A carbuncle is a painful infection involving an aggregate of contiguous follicles, with multiple drainage points and inflammatory changes in the surrounding connective tissue. Carbuncles commonly are found on the posterior neck and in persons with diabetes mellitus.[12] Although individuals with furuncles usually have no constitutional symptoms, carbuncles can be associated with fever, leukocytosis, and bacteremia. Both furuncles and carbuncles tend to heal with scarring.

The causative agent of furuncles and carbuncles is almost always *S. aureus*. The staphylococcal isolates (i.e., MSSA and MRSA) associated with furunculosis often possess the virulence factor Panton-Valentine leukocidin, a pore-forming toxin that targets neutrophils.[13,43,54] Conditions that predispose to furuncle formation include obesity, immunosuppression, diabetes mellitus, hyperhidrosis, maceration, friction, and pre-existing dermatitis.[43] Outbreaks of furunculosis have been reported in sports teams, families, and other settings with close contact.[12,55]

Recurrent furunculosis frequently is associated with carriage of *S. aureus* at multiple sites (e.g., nares, axillae, perineum) or with sustained close contact with someone who is a carrier. Rarely, children with recurrent furunculosis have an underlying immunodeficiency.[12] Other bacteria or fungi occasionally cause furuncles or carbuncles, and Gram stain and culture of the purulent exudate is indicated. The differential diagnosis of furuncles includes epidermal cysts, cystic acne, and hidradenitis suppurativa.

Treatment consists of frequent application of a hot, moist compress to promote drainage. Large furuncles and most carbuncles require surgical drainage, with disruption of any existing loculations and wound packing as appropriate.[12,13,43] When lesions are large, multiple, or associated with extensive cellulitis or fever, treatment with an oral antistaphylococcal agent is indicated. For recurrent furunculosis, eradication of staphylococcal carriage can be attempted. Attention to personal hygiene, bleach baths, or use of chlorhexidine soap may be beneficial.

Hand and Nail Infections

Paronychia

Acute paronychia is an infection of the soft tissue folds surrounding a fingernail or toenail. Infection occurs when minor trauma allows bacteria to enter the cuticle or nail fold. Paronychia is seen most commonly in children who suck their fingers, bite their nails or cuticles, or have poor hygiene. It also is associated with dishwashing, manicures, and use of artificial nails.

The lateral nail fold becomes warm, erythematous, edematous, and painful, and purulent fluid can accumulate underneath the nail plate. Usually only one nail is affected. In most cases, the infection is caused by *S. aureus* or mixed aerobic (i.e., *S. aureus*, S. *pyogenes*, and *Eikenella corrodens*) and anaerobic flora (i.e., *Bacteroides* spp., *Fusobacterium* spp., and gram-positive cocci).[56–58]

The diagnosis is based on clinical examination. Aerobic and anaerobic culture of purulent material is recommended to recover the pathogens and perform susceptibility testing of *S. aureus*. When exposure to oral flora is suspected (e.g., nail biting), a broad-spectrum oral antibiotic effective against anaerobes (i.e., clindamycin or amoxicillin-clavulanate) is indicated.[56] Warm compresses usually are curative for superficial lesions. In addition to oral antibiotic therapy, incision and drainage is needed for the treatment of deeper lesions with abscesses.

The differential diagnosis of acute paronychia includes chronic paronychia, psoriasis, and herpetic whitlow. Chronic paronychia is distinguished by the duration of symptoms and often is associated with *C. albicans*, usually in people whose hands are frequently exposed to water (e.g., finger sucking, dishwashers, house cleaners, bartenders, food handlers, nurses).[56,57] Herpes simplex virus infection of the fingers can occur after sucking or parental nail trimming by biting. Herpetic whitlow can resemble staphylococcal infection. Multiple coalescing vesicles of the digit associated with edema and a dusky appearance are typical of whitlow. Herpetic lesions should *not* be incised or debrided; instead, oral antiviral therapy should be given.[56,59] Reactivation recurrence is common.

Blistering Distal Dactylitis

Blistering distal dactylitis is an acral infection caused by *S. pyogenes* and less commonly by *S. aureus* or CoNS.[60,61] It usually is seen in children 2 to 16 years of age, but it has been reported in infants and adults.

The infection manifests as a tense nontender bulla with an erythematous base involving the distal volar fat pad of the phalanges.[60–63] Dark discoloration of the surrounding skin may be associated.[60] One or more digits can be affected, as can the nail fold, the volar surfaces of the proximal phalanges, the toes, and the palm.[61–63] Systemic symptoms usually are absent.[60–63] The blisters are filled with a thin, purulent fluid containing neutrophils and the infecting organisms.[60,61] Infections caused by *S. aureus* may be more likely to be associated with pain and involvement of more than one digit.[62]

The diagnosis is based on examination and culture. Treatment consists of incision and drainage or a 10-day course of systemic therapy, or both, using an agent with antistaphylococcal and antistreptococcal activity.[60,62,63]

Ulcerative Infections

Anthrax

Bacillus anthracis causes inhalational, gastrointestinal, meningeal, and cutaneous infections. Cutaneous anthrax in the United States is limited mainly to individuals who work with contaminated animals or animal products, including carcasses, hair, and wool. However, cases due to acts of bioterrorism have been reported.

Cutaneous infection occurs 1 to 7 days after exposure or inoculation of an endospore into the skin, usually at the site of a cut or abrasion.[64] Exposed sites such as the face, neck and arms are the most common locations.[65] The primary lesion is a small, painless, pruritic papule that transforms over a few days into a 1- to 2-cm bulla, which can be associated with satellite vesicles. Characteristic brawny, nonpitting edema surrounds the lesion. The bulla ruptures, forming an ulcer with a central black eschar[64,66] (Fig. 68.7). Malaise, low-grade fever, and regional lymphadenopathy are common.[64]

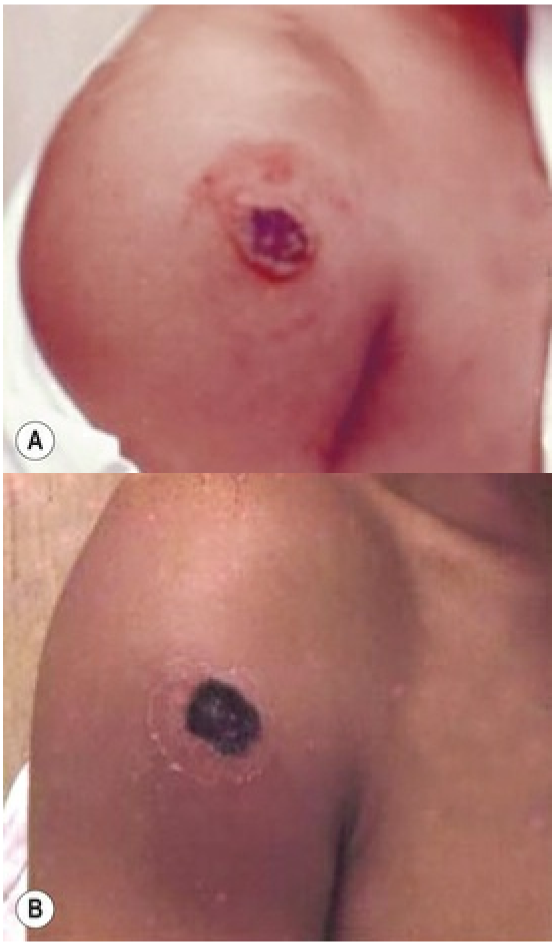

FIGURE 68.7 Cutaneous anthrax. (A) The ulcer has a vesicular ring, induration, and erythema. (B) As an eschar forms, induration lessens; surrounding

desquamation occurs, but erythema persists. (From Centers for Disease Control and Prevention.)

The differential diagnosis includes ecthyma, ecthyma gangrenosum, a furuncle, and necrotic arachnidism. Diagnosis is based on a Gram-stained smear, culture, or polymerase chain reaction (PCR) analysis of vesicular fluid, eschar, or tissue.[64,67] Incision and drainage of the lesion can precipitate bacteremia, but a skin biopsy of a lesion while administering antibiotic therapy likely confers minimal risk.[64,68] Recommendations for obtaining specimens are available from the Centers for Disease Control and Prevention (www.cdc.gov/anthrax/labs/recommended_specimen.html).

Treatment of mild, naturally occurring, cutaneous anthrax consists of penicillin or ciprofloxacin for 7 to 10 days. Cutaneous anthrax in children without systemic involvement associated with bioterrorism is treated with ciprofloxacin or doxycycline for 60 days due to the risk of inhalational exposure to the spores. Therapy can be modified based on antimicrobial susceptibility test results.[64,67]

Diphtheria

Cutaneous infection with *Corynebacterium diphtheriae* is rare in developed countries. It is seen mainly in travelers to endemic tropical areas,[41,69–71] the immunosuppressed, and those living in crowded, unsanitary conditions.[41,69] Infection can occur despite adequate immunization.[41,70]

Cutaneous diphtheria occurs in three forms: primary infection, which consists of a tender pustule that evolves into a punched-out ulcer with an adherent membrane and erythematous, edematous rim; secondary infection of a pre-existing ulcer or wound; and superinfection of eczematous skin lesions.[69,71] Lesional skin sheds bacteria for 2 to 6 weeks without treatment and is an important reservoir for person-to-person transmission and environmental contamination of pathogenic organisms, which can cause cutaneous and respiratory disease.[41,70,71] Systemic complications, including neurologic symptoms and myocarditis, are rare in immunized patients[70,71] and more often are associated with respiratory tract infection than cutaneous diphtheria.[41]

Culture of a lesion or its overlying membrane confirms the diagnosis, and laboratory personnel must be notified when *C.*

diphtheriae is suspected. Treatment consists of cleansing the affected skin and administering systemic antibiotic therapy with penicillin or erythromycin for 10 to 14 days.[41,71] The use of antitoxin in addition to systemic antibiotics is controversial[41,69] because cutaneous lesions are nontoxigenic or produce only small amounts of toxin.[71] To document eradication of the organism, two negative culture results should be obtained after treatment concludes.[41]

Ecthyma

Ecthyma is a rare, deep ulcerative infection of the skin that penetrates down to the dermis and is most commonly caused by *S. pyogenes*. Initially, a vesicle or vesicopustule with surrounding erythema develops; over time, the lesion evolves into a crusted ulcer with an elevated rim and heals with scarring. Lesions usually are located on the legs and frequently are associated with pruritic conditions such as insect bites or scabies. Lymphangitis, cellulitis, and poststreptococcal glomerulonephritis are potential complications of ecthyma.

Systemic antibiotic therapy with an agent effective against streptococci is recommended.[11] Noninfectious causes of ulcerative skin lesions such as pyoderma gangrenosum, vasculitis, cutaneous findings associated with Behçet disease, lymphomatoid papulosis, and factitial dermatitis should be considered if lesions do not improve with appropriate antibiotic therapy.

Ecthyma Gangrenosum

Ecthyma gangrenosum is the characteristic skin lesion associated with gram-negative organisms, especially *Pseudomonas aeruginosa*. *Pseudomonas* septicemia usually occurs in the setting of neutropenia or congenital neutrophil dysfunction, but it also has been described in healthy children, often younger than 1 year of age.[72]

Cutaneous findings are the result of a necrotizing bacterial vasculitis affecting small veins in the skin. Lesions begin as erythematous, indurated papules, vesicles, and nodules that progress over hours to days into a necrotic ulcer with a black eschar and an erythematous rim (Figs. 68.8 and 68.9). Lesions are most common on the gluteal and perineal areas, but they can occur anywhere.[73,74] Ecthyma gangrenosum also can manifest in a localized form, usually on the buttocks and legs, after inoculation of the organism into the skin. The localized form of ecthyma gangrenosum usually is not associated with bacteremia[11,74,75] and can occur in healthy children or those with occult immunodeficiency.[75]

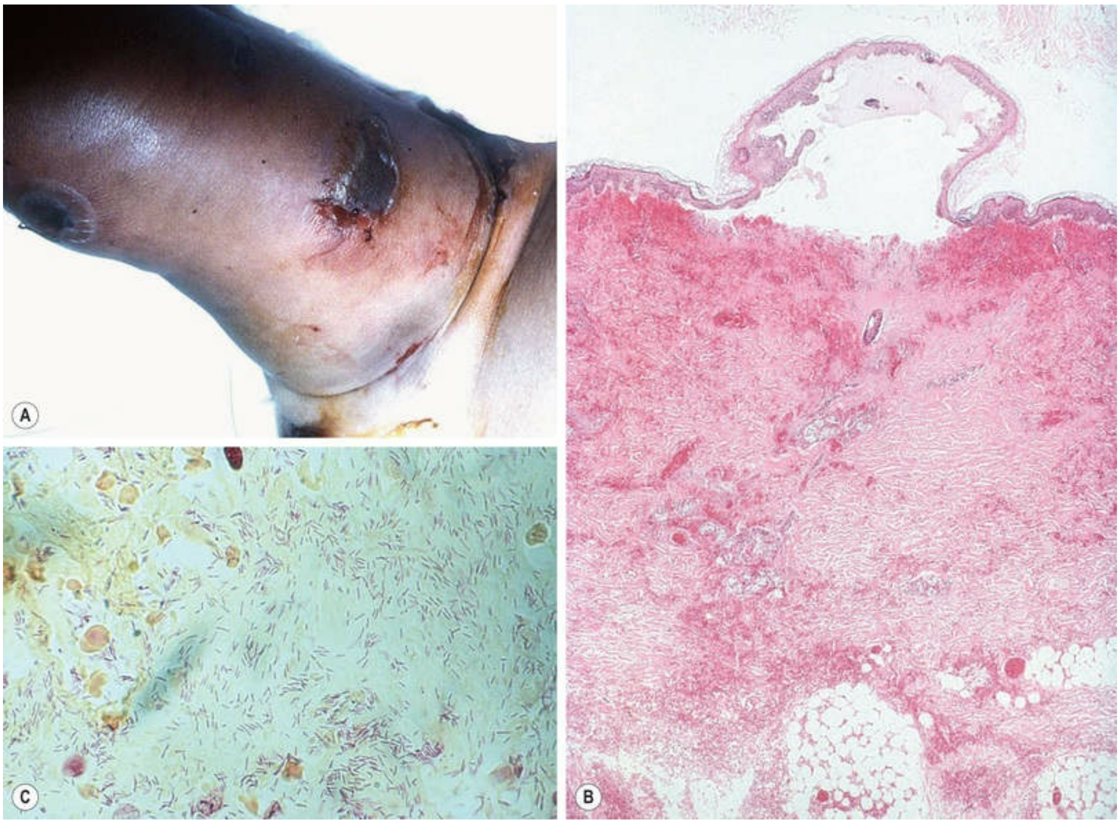

FIGURE 68.8 (A) *Pseudomonas aeruginosa* septicemia and ecthyma gangrenosum in a young boy with severe neutropenia. (B) Microscopic appearance of ecthyma gangrenosum in a fatal case of *P. aeruginosa* septicemia in an infant with leukemia. Haematoxylon and eosin stain shows superficial necrosis and elevation along with bland ischemic necrosis beneath. FIGURE 68.9 Ecthyma gangrenosum due to *Pseudomonas aeruginosa.* Necrotic ulcers with surrounding erythema and edema formed on the labium majus of a young girl with neutropenia and leukemia.

Culture of the lesions and blood cultures confirm the diagnosis. Ecthyma gangrenosum–like lesions can develop as a result of infection with other agents, usually in the setting of immunosuppression. Etiologic agents include gram-negative bacteria other than *P. aeruginosa,*[12,74] MSSA, MRSA[74] *Streptococcus* species,[75] *Candida* species, fungi (i.e., *Aspergillus, Mucor,* and *Fusarium* species),[12] and herpesviruses.[74] Effective treatment requires prompt initiation of an antibiotic effective against *P. aeruginosa* or other likely causative organisms.

Tularemia

Francisella tularensis can cause an ulcerative lesion associated with the bite of a tick or deer fly or direct contact with infected animals, most often rabbits or squirrels. Infection manifests in several different forms. The ulceroglandular form of tularemia is associated with cutaneous findings.

Lesions occur an average of 1 to 9 days after exposure[76] and begin as an erythematous, indurated papule or vesicle that may evolve into a punched-out ulcer with regional lymphadenopathy. Lesions can be accompanied by fever and malaise and can last for several weeks.[77] Papular eruptions, erythema nodosum, and erythema multiforme also can occur.[78]

The differential diagnosis includes anthrax, ecthyma, and other ulceroglandular infections, including glanders, bubonic plaque, and cat-scratch disease. If infection with *F. tularensis* is suspected, culture of the lesion is not recommended because of transmission to laboratory staff. Serologic testing is the primary method for confirming the diagnosis.[77,78]

Treatment with gentamicin or streptomycin for 10 days is preferred. Doxycycline or ciprofloxacin are alternatives.[76,77]

Soft Tissue Infections

Erysipelas

Erysipelas is a superficial skin infection affecting the upper dermis and the lymphatic system. In most cases, GAS is causative,[12,13,17,79] but group B, C, and G streptococci occasionally cause the infection,[12,79] and rarely, *S. aureus, Streptococcus pneumoniae, Klebsiella pneumoniae, Yersinia enterocolitica,* and *Haemophilus influenzae* are implicated as pathogens.[79]

Erysipelas has a bimodal age distribution; it is seen most often in young children and older adults.[12,79] Infection occurs when disruption of the skin barrier allows entry of organisms into the skin, and it often is associated with abrasions, leg ulcers, intertriginous or pedal fungal infections, insect bites, venous or lymphatic obstruction, and chronic edema.[12,13,79,80] In neonates, infection can originate at the umbilical stump and spread to the abdominal wall.[79]

The onset of erysipelas is abrupt and is characterized by a painful, bright red, shiny, edematous plaque with well-demarcated and slightly raised borders. In severe cases, necrosis and bullae can occur. Infection occurs on a lower extremity most often or the face, and it can be associated with regional lymphadenitis.[12,13,17,79] Fever, chills, and malaise can precede the onset of cutaneous manifestations. Potential systemic complications of erysipelas include septicemia, streptococcal toxic shock syndrome, endocarditis, and meningitis; however, complications are rare with prompt diagnosis and appropriate treatment.

The differential diagnosis includes contact dermatitis, burns, cellulitis, ecthyma gangrenosum, cutaneous findings associated with familial Mediterranean fever, and urticaria.[79] Diagnosis of erysipelas is made primarily on clinical grounds.[13,79] Blood culture, skin biopsy and needle aspiration have low yields.[12]

Treatment of erysipelas in immunocompetent patients consists of oral penicillin for 10 to 14 days, with follow-up after 48 to 72 hours to ensure the infection is improving. Patients with severe infections, young infants, and immunosuppressed patients may require hospitalization for parenteral therapy.[79] For penicillin-allergic patients, macrolide (depending on regional rates of resistance), clindamycin, or linezolid therapy is considered.[12,79] An antistaphylococcal antibiotic should be used.[12] Local wound care and attention to predisposing factors (e.g., treating tinea pedis, elevating edematous legs) are important aspects of care. Prophylactic therapy is considered infrequently for patients with recurrent disease.[12,79]

Cellulitis

Cellulitis is an acute infection of the skin involving the dermis and subcutaneous tissues that manifests as edema, warmth, erythema, and tenderness of the skin. The lateral margins of cellulitis tend to be indistinct, unlike the well-demarcated borders of erysipelas (Fig. 68.10). Vesicles, bullae, and petechiae can occur on involved skin. The lower legs are affected most commonly, but infection can occur at any site. Associated findings include lymphangitis, regional lymphadenopathy, fever, chills, and malaise. Predisposing factors for cellulitis include pre-existing skin infections (e.g., ecthyma, impetigo), breaks in the skin due to trauma or insect bites, lymphatic obstruction or other causes of edema, leg ulcers, and obesity.[12,13] When cellulitis occurs in a periorbital distribution, especially in the absence of a break in the skin, orbital cellulitis should be considered.

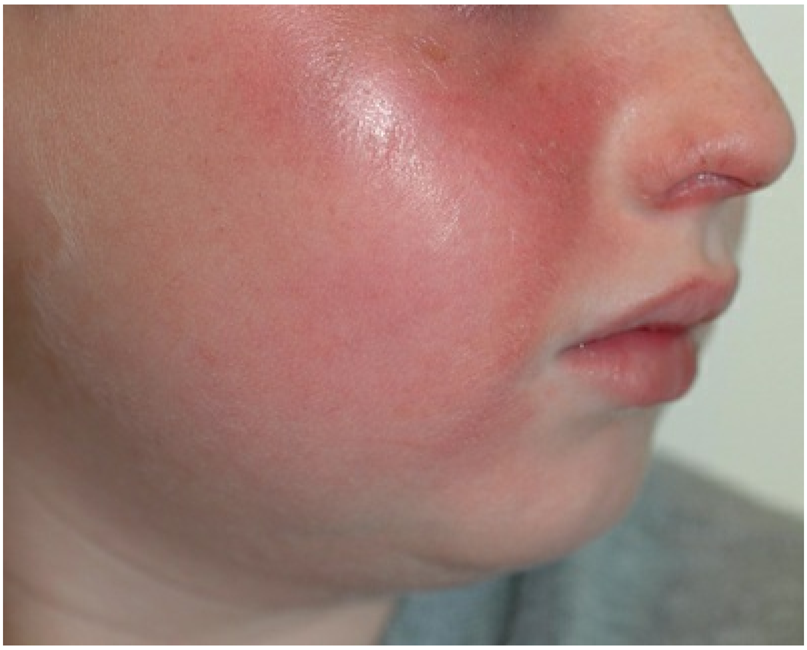

FIGURE 68.10 Ill-defined erythema and edema on the cheek of a boy with cellulitis. (Courtesy of Brandon Newell, MD, Kansas City, Missouri.)

The most common etiologic agents are *S. pyogenes* and *S. aureus*.[12,43] When facial cellulitis in children is associated with a portal of entry such as a tooth abscess, bite wound, or cutaneous trauma, oral anaerobic bacteria can be causative.[81] *H. influenzae* type b (Hib) was an important cause of periorbital[13] and facial cellulitis without a skin site of injury or infection in children 3 months to 3 years of age before the introduction of the conjugate vaccine. Hib cellulitis has a characteristic bluish discoloration resembling a bruise and often is associated with bacteremia.[82] Bacteremic *S. pneumoniae* can cause facial cellulitis in children resembling that due to *H. influenzae*.[83] In patients who are immunocompromised or have been exposed to animals or special conditions, other bacterial or fungal agents must be considered (Table 68.3).

TABLE 68.3
Special Causes of Cellulitis

Setting or Exposure	Causes of Cellulitis
Cat or dog bites	*Pasteurella* species, *Capnocytophaga canimorsus*
Penetrating trauma	*Staphylococcus aureus*
Freshwater immersion	*Aeromonas hydrophila*
Saltwater immersion	*Vibrio* species
Freshwater, saltwater fish	*Streptococcus iniae*
Swine, poultry, fish	*Erysipelothrix rhusiopathiae*

Periorbital or facial cellulitis	*Haemophilus influenzae, Streptococcus pneumoniae*
Neutropenia	*Pseudomonas aeruginosa,* other gram-negative bacilli
Human immunodeficiency virus infection	*Helicobacter cinaedi*
Acute varicella	*Streptococcus pyogenes*
Immunosuppression	*Cryptococcus neoformans*

Diagnosis is based on physical examination and a detailed history to elicit factors predisposing to cellulitis due to a less common pathogen. Blood culture should be performed in the setting of young age or systemic illness; otherwise, the yield is low.[84] Culture of an aspirate from the site of inflammation yields a pathogen in 10% of patients,[85] with an aspirate taken from the point of maximum inflammation yielding the causal organism more often than does a leading-edge aspirate.[86] Tissue culture is positive for 18% to 20% of patients, and the density of organisms is low,[85,87] although a higher density of organisms has been found in specimens taken from a site near an ulcer.[87] Culture of a primary lesion (e.g., ulcer, abrasion) corresponds to that of a tissue culture and can avoid a more invasive procedure.[85] Due to low yield, aspirates and tissue cultures usually are reserved for cases of severe or atypical cellulitis or for patients who are immunocompromised or are not responding to empiric therapy.

Uncomplicated cellulitis in immunocompetent patients should resolve with antimicrobial therapy targeting streptococci and staphylococci. If fever and lymphadenopathy are absent, outpatient treatment using a penicillinase-resistant penicillin, first-generation cephalosporin, or clindamycin is appropriate.[12,13] The need for an agent providing coverage for community-associated MRSA should be guided by local prevalence and antibiotic susceptibilities. Parenteral therapy is instituted for fever, rapid progression, lymphangitis, or lymphadenitis. When erythema, warmth, edema, and fever have decreased substantially in uncomplicated cases, a 10-day course of treatment can be completed with oral therapy. Adjunctive care includes elevation of the affected extremity, analgesic for pain, and tetanus immunization when appropriate.[17]

Erysipeloid

Erysipeloid is a rare, acute cutaneous infection resulting from traumatic inoculation of *Erysipelothrix rhusiopathiae* into the skin. Infection usually occurs in patients with occupational exposure to raw fish, poultry, and meat products[88,89] or to contaminated animals, especially swine.[88]

Localized cutaneous infection manifests as a well-demarcated, erythematous-to-purple inflammatory plaque with raised borders on the dorsal aspect of one hand or fingers, and it typically occurs 2 to 7 days after inoculation. The lesion spreads peripherally and can display central clearing.[88,89] Vesicles, bullae, and edema of the fingers sometimes are seen. Lesions can be asymptomatic or associated with pain, pruritus, or fever.[88]

Untreated, limited cutaneous infection can resolve spontaneously after 2 to 3 weeks, but it can recur weeks to months later.[89] Rarely, a diffuse cutaneous form of infection occurs, manifesting as lesions over several areas of the body,[88,89] and it may be associated with fever, lymphadenopathy, myalgia, and arthralgia. Rare systemic complications of erysipeloid include encephalitis, meningitis, endocarditis, pyogenic arthritis, and sepsis.[88]

E. rhusiopathiae is difficult to isolate, although tissue culture of the advancing edge of the lesion can identify the organism.[89] Diagnosis is based mainly on the patient's occupation or exposure history, clinical findings, and rapid improvement with antibiotic therapy. The recommended treatment for localized cutaneous infection is penicillin or a cephalosporin for 7 days, with improvement usually seen after 2 to 3 days.[88]

Erythematous Macules and Papules

Brittany S. Barros, Andrea L. Zaenglein

Approach

Differentiating rashes due to infection from other common cutaneous eruptions, particularly adverse drug eruptions, can be difficult. Recognizing the differences in presentation and using proper terminology for erythematous exanthems are the initial steps.

The commonly used (and often overused) term *maculopapular* describes a rash that has both macular and papular components at some time during the course of the disease. *Morbilliform* (i.e., measles-like) is used to describe uniform lesions that have coalesced. *Scarlatiniform* is used when the exanthem resembles scarlet fever (i.e., has a sandpaper feel and is confluent in the flexural areas). If lesions are generalized but remain discrete, the term *rubelliform* may be used.

Secondary characteristics should be added to further describe the exanthem; *annular, lacy, reticulated, evanescent, urticarial, petechial,* and *purpuric* are useful descriptors. Color is described in shades, and erythema can range from faint pink to violaceous red.

Many of the classic exanthems, such as measles, rubella, and erythema infectiosum, are associated with macules or papules on the skin. Differentiating common and uncommon causes of infectious rashes often is difficult because the patterns are not always unique to a specific infectious agent. Detailed and accurate history taking is vital to making a correct diagnosis (Box 69.1). The patient's age and pre-existing conditions are important because many infectious rashes occur predominantly within a specific age range or in the context of another illness.

Box 69.1

Questions Used to Elucidate the Causes of Exanthems

- What time of year did the rash start?
- Where on the body did the rash start, and how has it evolved?
- Is the eruption localized or generalized?
- Does the rash come and go? Over what timeframe?
- Is the rash worse at a specific time of day? Is the rash made worse by the sun?
- Is there an associated enanthem?
- Is the rash pruritic, painful, or asymptomatic?
- Are there other symptoms, such as joint swelling, fever, adenopathy, vomiting, cough, headache, or photophobia?
- Is there a recent history of use of any medications, including over-the-counter medications?
- Has there been a recent illness?
- Has there been recent exposure to another person with a similar illness? Is the child in group childcare or school?
- Are immunizations up to date?
- Is there an immunocompromising condition or drug?
- Where was the child born? Has there been recent travel?
- Has there been recent exposure to pets, wildlife, or biting insects?

- What evaluations, including laboratory studies and cultures, have been done already?

- Has treatment been given? Was the treatment effective?

Etiologic Agents, Epidemiology, and Pathogenesis

Macular and papular exanthems can result from numerous infectious causes. An extensive list of viral and nonviral causes is shown in Box 69.2. In children, enteroviruses are by far the most common cause of morbilliform rash with febrile illness, especially for those younger than 1 year of age[1] (Fig. 69.1). Enteroviruses have a marked seasonality, with an increase in prevalence in the summer and a large peak in August and autumn. Parvovirus B19, the etiologic agent of erythema infectiosum, is the maculopapular rash most commonly identified in children 4 through 10 years of age.[2] The exanthem is typified by bright red macules on the cheeks that spare the nasolabial folds (Fig. 69.2), followed by the development of reticulated lacy pink macules and thin papules on the extremities that can persist for up to 3 weeks. Measles occurs as sporadic imported cases or in high-profile outbreaks in the United States and is still prevalent worldwide. Measles is characterized by the classic morbilliform rash accompanied by fever and the three Cs: cough, conjunctivitis, and coryza.[3]

Box 69.2

Infectious Conditions That Cause Macular and Papular Exanthems

Viruses

Human Herpesviruses

Erythema multiforme

Varicella

Shingles

Mononucleosis

Pityriasis rosea

Roseola infantum

Poxviruses

Smallpox

Vaccina

Orf disease

Milker nodules

Cowpox

Molluscum contagiosum

Polyomaviruses

Trichodysplasia spinulosa

Picornaviruses (Coxsackievirus and Echovirus)

Nonspecific exanthems

Hand-foot-and-mouth disease

Boston exanthem

Eruptive pseudoangiomatosis

Paramyxoviruses

Measles

Rubella

Parvoviruses

Erythema infectiosum

Papular-purpuric gloves and socks syndrome

Arboviruses

West Nile fever

Dengue

Alphavirus

Human Papillomaviruses

Warts

Retroviruses

Human T-lymphotropic virus 1 infection

Conditions With Likely Viral Causes

Gianotti-Crosti syndrome

Unilateral laterothoracic exanthem

Bacteria

Impetigo

Folliculitis

Paronychia

Staphylococcal scalded skin syndrome

Toxic shock syndromes

Scarlet fever

Erysipelas

Cellulitis

Perineal dermatitis

Rheumatic fever

Erythrasma

Actinomycosis

Ecthyma

Hot tub folliculitis

Meningococcemia

Gonococcemia

Salmonellosis

Glanders

Cat-scratch disease

Bacillary angiomatosis

Rat-bite fever

Tularemia

Brucellosis

Ehrlichiosis

Anaplasmosis

Leptospirosis

Lyme disease

Secondary syphilis

Yaws

Pinta

Rickettsia

Epidemic typhus

Endemic typhus

Rocky

Mountain spotted fever

Mediterranean spotted fever

African tick bite fever

Yucatan spotted fever

Japanese spotted fever

North Asian tick-bite fever

Queensland tick typhus

Scrub typhus

Rickettsialpox

Q fever

Protozoa

Amebiasis cutis

Leishmaniasis

Trypanosomiasis

Toxoplasmosis

Helminths

Trematodes

Freshwater swimmers' itch

Saltwater marine dermatitis

Nematodes

Pinworms (can cause generalized papules)

Hookworms

Larva migrans

Onchocerciasis

Fungi

Dermatophytes

Tinea capitis

Tinea corporis

Tinea faciei

Tinea cruris

Majocchi granuloma

Early Cutaneous or Deep Fungal Infections

Blastomycosis

Histoplasmosis

Coccidioidomycosis

Phaeohyphomycosis

Chromomycosis

Sporotrichosis

Fusariosis

Aspergillosis

Alternaria infection

Yeast

Candidiasis

Tinea versicolor

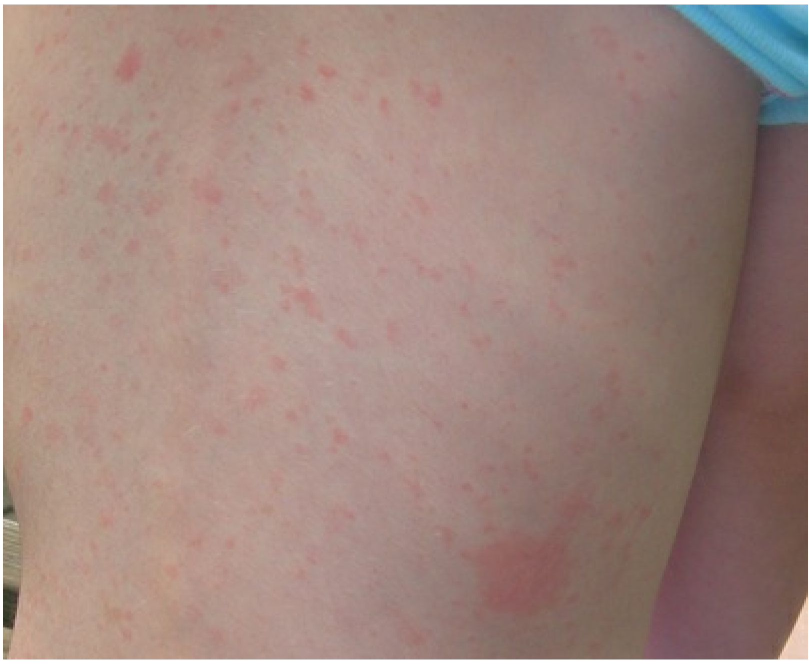

FIGURE 69.1 Discrete, confluent, erythematous, pink, blanchable papules are associated with enterovirus infection.

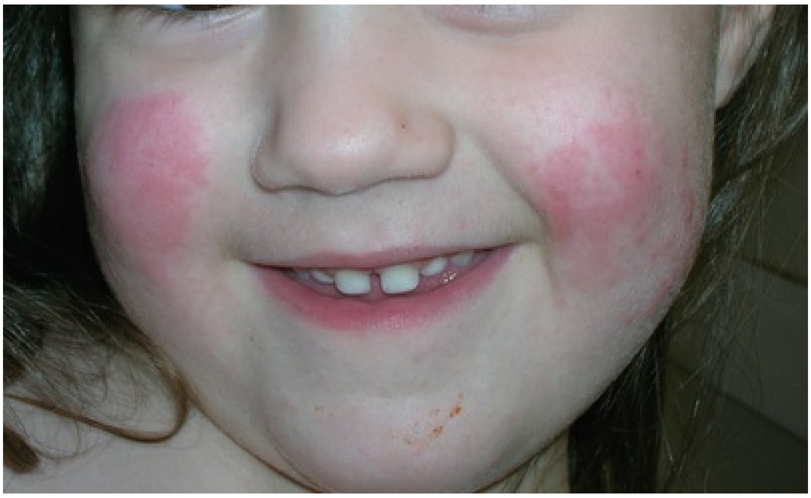

FIGURE 69.2 Bilateral, bright red, macular erythema of the cheeks is typical of parvovirus infection.

Maculopapular rashes in children also can be indirectly related to an infectious agent. An estimated 1.2% to 12% of children develop cutaneous adverse reactions to medications, especially antibiotics.[4] Many cutaneous adverse drug eruptions (CADEs) are indistinguishable from viral exanthems because they have a similar morphology and course (Fig. 69.3). In the case of mononucleosis caused by Epstein-Barr virus, the administration of an antibiotic (classically ampicillin) can lead to a florid maculopapular rash in about 3% of children.[5] More severe CADEs, including Stevens-Johnson syndrome and toxic epidermal necrolysis, can manifest with macules and papules before progressing to blistering. Mucosal involvement in this setting should alert the clinician to this possibility.

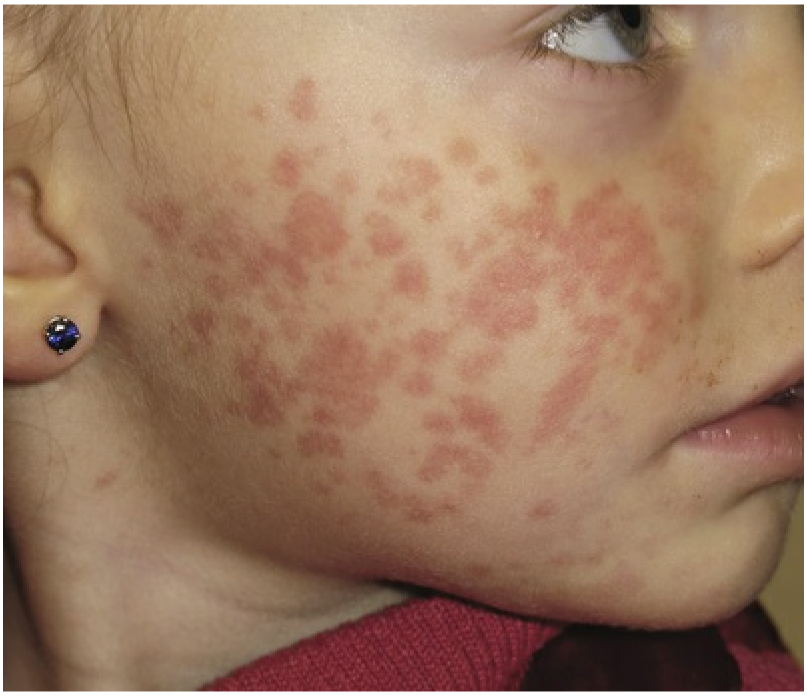

FIGURE 69.3 Many cutaneous adverse drug eruptions are indistinguishable from viral exanthems. The generalized, pink, erythematous macules occurred on a 2-year-old child with an upper respiratory infection that was treated with amoxicillin.

A drug reaction with eosinophilia and systemic symptoms (DRESS) is another severe CADE manifesting with a widespread morbilliform eruption and often with pronounced facial swelling associated with variable systemic involvement, including liver, renal, and pulmonary dysfunction. Type 4 delayed hypersensitivity and reactivation of human herpesvirus 6 have been postulated in the etiopathogenesis of this CADE.[6]

Common noninfectious causes of macular and papular exanthems are listed in Table 69.1. These disorders should be considered in the differential diagnosis.

TABLE 69.1

Common Noninfectious Causes of Macular and Papular Exanthems

Predominantly Papules	Predominantly Macules	Macules and Papules
Insect bites Acne Keratosis pilaris Miliaria	Sunburn Dermatomyositis Systemic lupus erythematosus	Adverse drug eruptions • Urticarial drug reaction • Morbilliform drug reaction • Early Stevens-Johnson syndrome or toxic

Granuloma annulare Cnidarian stings		epidermal necrolysis • Drug reaction with eosinophilia and systemic symptoms (DRESS) Atopic dermatitis Seborrheic dermatitis Guttate psoriasis Contact dermatitis Polymorphous light eruption

Vesicles and Bullae

James Treat

Vesicles and bullae (i.e., blisters) result from a disturbance of epidermal or basement membrane connections, creating spaces that allow fluid collection. Blisters can be caused directly by bacterial, viral, and fungal infections or be a reactive phenomenon to an infection. Diagnosis of vesiculobullous eruptions must be made promptly because although some conditions are benign, others are rapidly progressive and rarely life-threatening.

The skin consists of epidermis, composed primarily of keratinocytes, and an underlying dermis of connective tissue (Fig. 70.1). The basement membrane zone anchors the epidermis to the dermis. Cohesion between layers of the skin is weakest in the epidermis at the stratum corneum–spinous cell transition zone and within the least electron-dense region of the basement membrane zone, called the *lamina lucida*. A plane of cleavage (i.e., blister) is most likely to develop at these levels (see Fig. 70.1). The Nikolsky sign results when application of a lateral, sliding force to nonblistered skin (usually at a site of erythema or adjacent to a bullous lesion) produces a plane of cleavage. This maneuver can be useful in the clinical recognition of a blistering disorder but cannot be used to judge the depth of the blister in the skin.

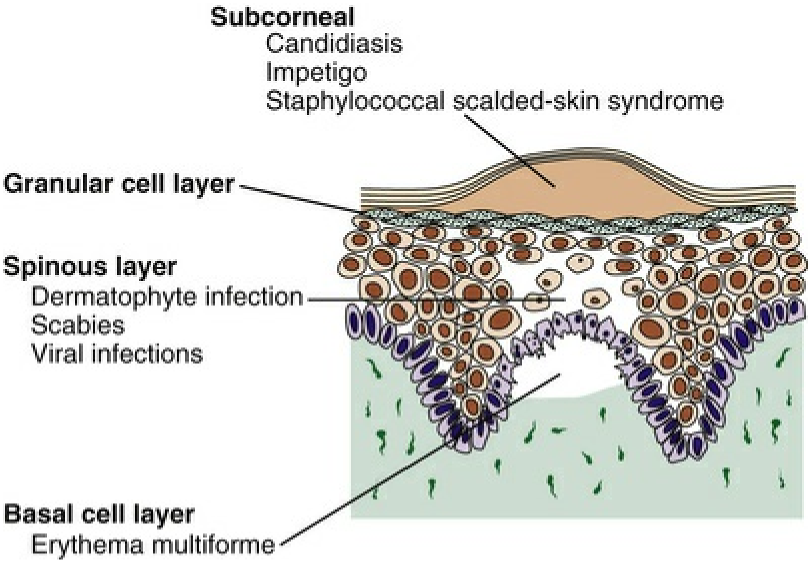

FIGURE 70.1 Sites of vesiculobullous diseases in the skin.

Vesicles and bullae are circumscribed, elevated lesions filled with clear fluid. Depending on the mechanisms responsible for their formation, blisters can contain a combination of serous or lymphatic fluid, serum proteins, antigen-antibody complexes, and soluble inflammatory mediators. Cellular elements can include inflammatory cells, erythrocytes, detached epidermal cells, and infectious agents. Vesicles measure less than 1 cm in diameter, and bullae are 1 cm or larger. Vesicles and bullae associated with infection can be solitary, such as the lesion of streptococcal blistering dactylitis; localized, as in staphylococcal bullous impetigo; grouped or clustered, as in herpes simplex virus (HSV) infection; arranged in a dermatome, as in herpes zoster; or generalized, as in chickenpox.

A vesicle or bulla that is located in the epidermis tends to be *flaccid* and to rupture easily. When located subepidermally, bullae typically are *tense,* have greater structural integrity, and rupture less easily. As a vesicle or bulla matures, an influx of leukocytes and accumulation of cellular debris can occur, leading to development of a *pustule*. Depending on the cause of the inflammatory response, a pustule can be infected or sterile.

Rupture and detachment of the roof of a subcorneal or intraepidermal blister leads to a moist, slightly depressed *erosion*. Erosions do not extend below the epidermal-dermal junction and heal without scarring. Postinflammatory pigmentary changes, however, can exist for weeks to months. When an unroofed blister extends into the dermis or subcutaneous tissue, it forms an *ulcer*. Scarring or postinflammatory pigmentary changes can follow healing of a wound that involves the dermis. Erosion or ulceration is accelerated in areas of friction or maceration, such as in the axillae or perineum, and on the mucous membranes of the oropharynx and vagina. *Crusts* or *scabs* are the dried remnants of serum, blood, and cellular debris. They form quickly over denuded areas.

It is not unusual for several types of lesions to occur at the same time in an individual. For example, the eruptions caused by varicella can comprise a variety of lesions in various stages of evolution, including macules, papules, vesicles, and pustules, mixed with erosions, ulcers, crusts, and self-induced linear excoriations. Bullae can form if staphylococcal superinfection occurs (Fig. 70.2).

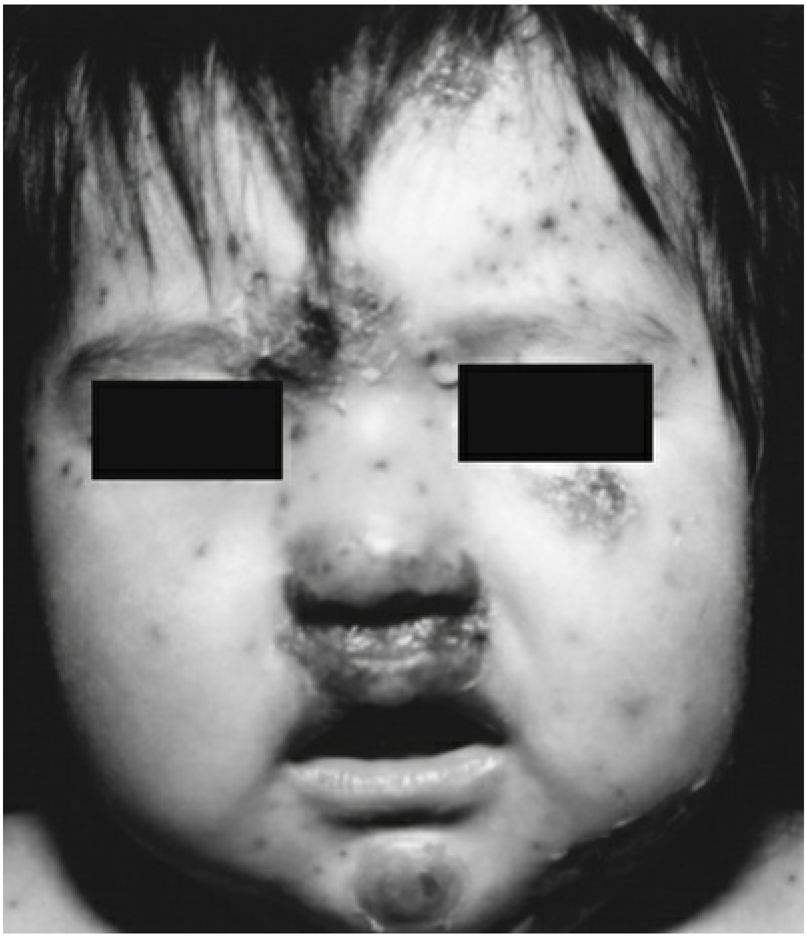

FIGURE 70.2 Chickenpox lesions that are infected secondarily with *Staphylococcus aureus* form crusted plaques and bullae on the face of an infant.

Etiology and Clinical Manifestations

Although the list of infectious agents capable of causing vesiculobullous rashes is lengthy, the most common agents are enteroviruses, varicella-zoster virus (VZV), HSV, *Staphylococcus aureus,* and *Streptococcus pyogenes*. The list of noninfectious conditions that closely mimic the eruption caused by these organisms also is lengthy, often leading to a difficult or delayed diagnosis.[1–3]

The cause of a vesiculobullous infection frequently can be established by consideration of the epidemiologic context. Differentiating the morphology, distribution, and evolution of the eruption is key to diagnosis. The season, patient age, history of recent exposure to infectious agents or medications, previous disease, and concurrent symptoms are factors to be considered. Categorization based on depth (i.e., tense or flaccid) and the predominant size (i.e., vesicles or bullae) also can aid the diagnosis (Table 70.1).

TABLE 70.1

Clinical Features of Blistering Skin Disorders by Etiologic Agent

Infection or Reaction Pattern	Type of Blister	Size	Usual Locations	Other Clinical Signs and Symptoms
Herpes simplex virus	Tense	Vesicles	Most often mucosal or perimucosal	Clustered and painful
Zoster (varicella-zoster virus reactivation)	Tense	Vesicles	Any dermatome	Clustered in a dermatome or disseminated in immunocompromised
Hand-foot-and-mouth disease (enterovirus infection)	Tense	Vesicles	Palms, soles, oral mucosa, and buttocks	Vesicles tend to be oval and on the hands and feet, following dermatoglyphics
Bullous impetigo	Flaccid	Vesicles or bullae	Perioral or perineal	Honey-colored crusting
Staphylococcal scalded skin syndrome	Flaccid, superficial epidermis only	Large bullae	First manifests in intertriginous areas, then can be widespread	Age <5 yr
Dactylitis	Tense	Bullae	Digits	Painful and red
***Vibrio vulnificus* infection**	Tense	Bullae	Feet	Purple edematous (typically on extremity) with tense bullae

Necrotizing fasciitis	Tense	Bullae	Any site	Hyperesthetic or anesthetic purpuric skin
Bullous tinea	Tense	Vesicles or bullae	Feet	Annular or interdigital scaling
Stevens-Johnson syndrome	Flaccid, full thickness of epidermis	Vesicles or bullae	Face and orofacial, any site	Exuberant mucosal involvement (lips, oral mucosa, eyes, perineum)

Infections Associated With Vesicles

Cutaneous HSV infection typically manifests as 1- to 4-mm vesicles that appear in clusters corresponding to the distribution of the infected nerve or primary inoculation site. Mucosa and periorificial areas tend to have microabrasions and are more susceptible to infection. Primary HSV infections can be exuberant and lead to extensive vesiculation especially in the mouth (i.e., primary herpetic gingivostomatitis). Recurrences of HSV usually are localized, and unless the patient is immunocompromised, they may lead only to edematous, crusted papules (Fig. 70.3). HSV infecting digits (i.e., whitlow) usually causes a tense, larger bulla made of many individual vesicles that are held together by the thick acral skin. This often produces a honeycomb pattern of loculated vesicles. Recurrent, clustered vesicles, crusts, or pustules in a fixed spot, even if not mucosal, should alert the clinician to the possibility of HSV infection. Longstanding, crusted ulcerations are a common presentation in immunocompromised patients when the HSV infection cannot be cleared adequately.

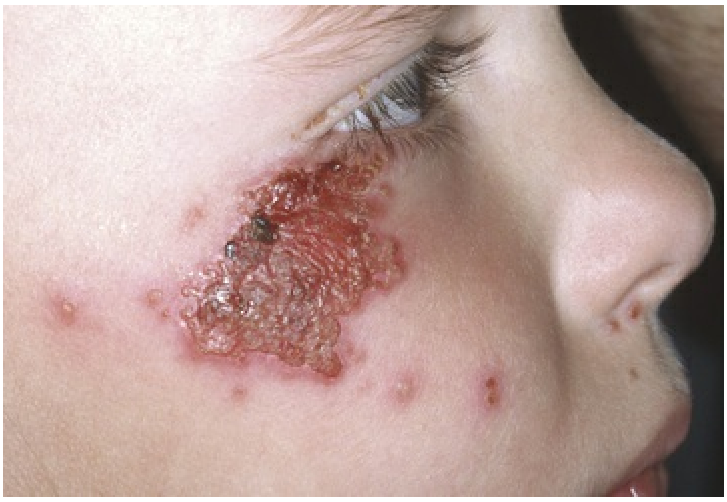

FIGURE 70.3 A young girl hospitalized for febrile

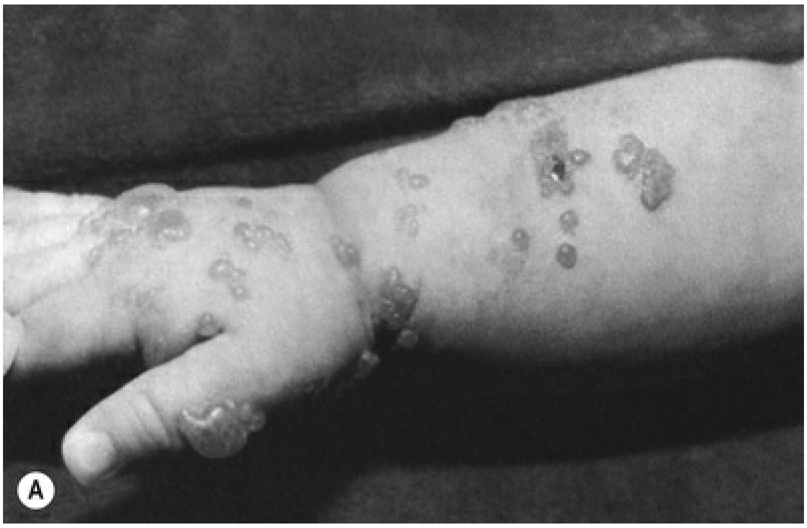
pneumonia had reactivation herpes simplex virus 1 in a dermatomal distribution on her face. (Courtesy of J.H. Brien, ©.)

Zoster is cutaneous reactivation of the VZV virus that corresponds to the sensory nerve in which VZV had been dormant. The initial manifestation may be painful, red papules clustered in a plaque that then vesiculate over a few days and finally crust and leave erosions. The key to diagnosis is the dermatomal distribution (Fig. 70.4). Children may have one to three adjacent dermatomes involved in uncomplicated zoster, which can occur after vaccination but is more common in children who had chickenpox and especially when chickenpox occurred at less than 1 year of age. Most children with zoster are otherwise healthy. Dissemination from an initial dermatomal cluster, involvement of multiple noncontiguous dermatomes, or a concerning review of systems should alert the clinician to the possibility of underlying immunocompromising conditions.



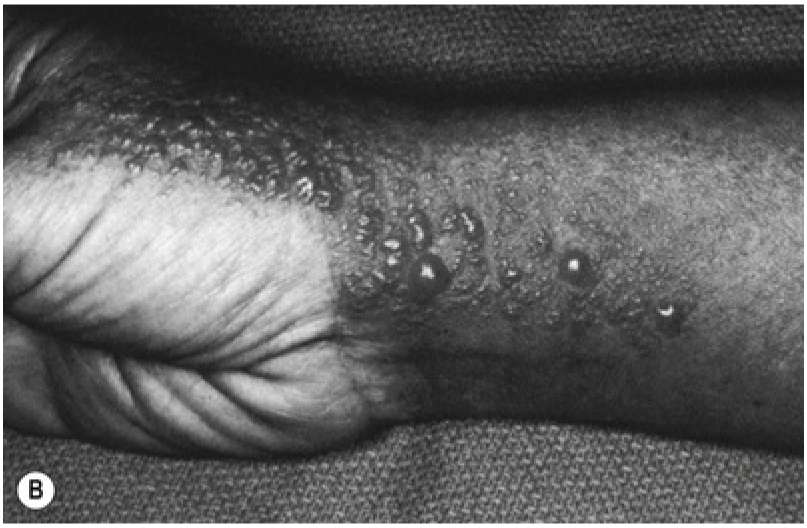


FIGURE 70.4 (A) Bullae on the dorsal hand and forearm of an infant resulted from reactivation of varicella-zoster virus without superinfection. (B) Vesicles and bullae on the hand and wrist of a girl with contact dermatitis were caused by poison oak.

Primary varicella (i.e., chickenpox) and disseminated VZV in immunocompromised patients manifest as widely distributed, crusted papules and vesicles on a red base ("dew drops on a rose petal")

Hand-foot-and-mouth disease (HFMD) is caused by enteroviruses, including coxsackievirus A16, enterovirus 71, and enterovirus A6. HFMD manifests with vesicles anywhere in the mouth (including the tongue) and on the palms, soles, and buttocks. The oral mucosa, which has thin epithelium without stratum corneum, allows vesicles to rupture easily, and it is more common to see only erosions. Conversely, the palms and soles have a thick epidermis, and the vesicles may appear as red macules; it can be difficult to detect the fluid inside. Vesicles on the palms and soles tend to be oval and follow the dermatoglyphics (i.e., fingerprint markings).

Enterovirus A6 has become more prevalent in the United States.[4] Enterovirus A6 infection often manifests with more exuberant HFMD, with larger and more widespread vesicles and bullae that also can occur on acral surfaces such as on the dorsum of feet, hands, and knees. Enterovirus A6 occurring in conjunction with atopic dermatitis can lead to eczema coxsackium.

Infections Associated With Flaccid Bullae

Bullous impetigo is an acute blistering infection caused by *Staphylococcus aureus* group II, typically phage 71 infection. This strain of *S. aureus* carries exfoliative toxin A, which specifically targets and disrupts the intraepidermal keratinocyte connection desmoglein 1 (DSG1).[5] Because DSG1 is most important for intracellular keratinocyte adhesion in the top layers of the epidermis, lesions in bullous impetigo tend to be flaccid and rupture easily. Drying of the ruptured blister and serous fluid results in honey-colored crusting. The function of DSG1 is duplicated in the mucosa by coexpression of DSG3. Because DSG3 is not targeted by the exfoliative toxin, there is no mucosal blistering in bullous impetigo or in staphylococcal scalded skin syndrome (SSSS) (discussed later).

Dissemination of the exfoliative toxin A can cause cleavage of DSG1 distant from the initial infection, resulting in SSSS. Clinically, the cleavage manifests as bright red patches of painful skin that easily shear off with friction because the bullae are superficial. The most common sites for bullae include the neck, axillae, inguinal folds, and periorificial areas (Fig. 70.5). SSSS is more common in children younger than 5 years of age.

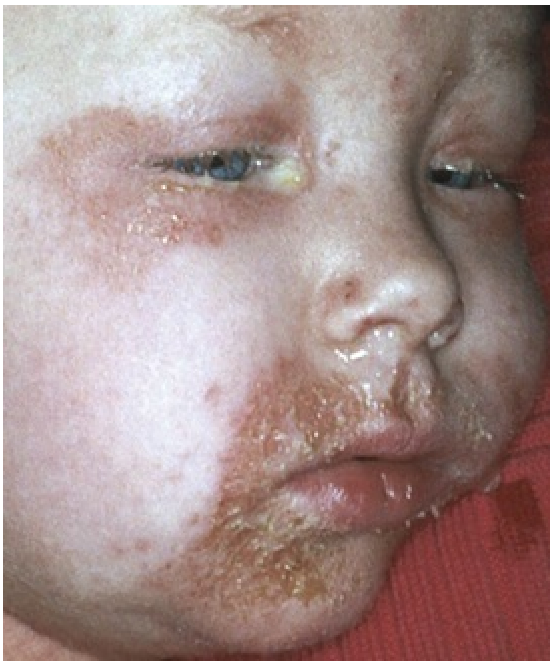

FIGURE 70.5 Staphylococcal scalded skin syndrome in a toddler. (Courtesy of J.H. Brien, ©.)

Infections Associated With Tense Bullae

Blistering distal dactylitis classically is caused by *S. pyogenes* infection. It manifests as tense, firm, single or multiple vesicles and bullae that typically occur on the volar surface of the fingers.

Gram-negative septicemia can lead to *purpura fulminans*. The clinical phenotype is characterized by large, purpuric patches with hemorrhagic, sometimes tense bullae due to vascular damage and epidermal necrosis.

Necrotizing fasciitis also comes to medical attention with large, tense bullae (often hemorrhagic) due to underlying dermal necrosis.

Dermatophyte infections typically cause round, scaling plaques, but if the burden of fungus and inflammation is large enough, a split can occur, typically deep in the epidermis or at the dermoepidermal junction, that leads to tense bullae. This occurs most commonly on the feet but also can occur on the trunk or extremities.

Vesiculobullous Disease Induced by Infection

Stevens-Johnson syndrome (SJS) is a severe, life-threatening, necrotic mucocutaneous reaction. The hallmark is severe mucosal involvement that typically involves the lips, oral mucosa, and conjunctivae and sometimes involves the urethra, anus, and vagina (Fig. 70.6).

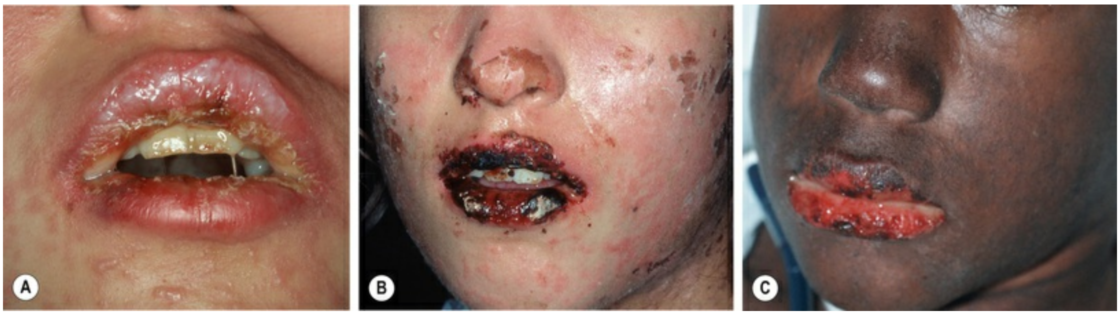

FIGURE 70.6 Adolescents with Stevens-Johnson syndrome in stages of development (A) and resolution (B and C). (Courtesy of J.H. Brien, ©.)

The classic cutaneous lesion has a target appearance characterized by a red-purple macule or patch with central duskiness, which can vesiculate or form large bullae. Traumatized areas can shear off and leave only deep erosions. Medications are the most common cause of SJS. *Mycoplasma pneumoniae* also can induce typical SJS or SJS with a predominant mucosal involvement and few or no cutaneous lesions.[6] SJS is differentiated from SSSS by the predominance of mucosal involvement and the full-thickness epidermal necrosis that typically leads to tense bullae and deeper wounds in SJS.

Diagnosis

To diagnose an infectious cause of a blister, an intact blister can be cleansed with alcohol, the edge incised, and the fluid collected for Gram stain and culture. If there are no intact blisters, the base of an erosion can be swabbed for culture; growth of normal skin flora must be interpreted in context. A potassium hydroxide preparation or fungal culture from the unroofed blister specimen can be used if dermatophyte infection is suspected. Viral causes of blisters can be diagnosed by culture, polymerase chain reaction (PCR), or direct fluorescent antibody testing. A Tzanck smear showing multinucleated giant cells with nuclear molding can rapidly diagnose HSV and VZV infection but is less sensitive than other tests. The flaccid bulla in SSSS typically is sterile because the blister is caused by the toxin distant from the primary infection. A primary site of infection or colonization can be investigated.

The diagnosis of SJS can be made rapidly by evaluation of a frozen section skin biopsy for histologic evidence of full-thickness epidermal necrosis. If there is no inciting medication, *Mycoplasma* serology or PCR can be used to investigate possible causality. The differential diagnosis of noninfectious vesiculobullous eruptions in children includes autoimmune blistering disorders such as linear IgA deposition (i.e., chronic bullous disease of childhood), epidermolysis bullosa, thermal or friction injury, contact dermatitis, bullous mastocytoma, and incontinentia pigmenti. In addition, the so-called salt and ice challenge, which is commonly done intentionally by adolescents as a dare, causes a type of thermal injury that can mimic severe cellulitis or necrotizing fasciitis. When salt is applied to the skin followed by ice, the ice can rapidly freeze the skin, leading to hemorrhagic bullae and crusting. The pattern often is geometric and is seen in areas that are easily accessible (e.g., arms, legs, chest).

After discontinuing an offending drug, the management of SJS is controversial, especially the use of corticosteroids and intravenous immune globulin. It has been reviewed by Wolf and Davidovici.[7]

When the cause of vesicular lesions remains in doubt, culture, biopsy for histopathologic evaluation, and immunofluorescence staining are helpful, particularly to exclude noninfectious bullous disorders.[1]

Purpura

Melissa A. Reyes, Lawrence F. Eichenfield

Purpura is a significant finding, especially because it has been associated with multiple infectious causes, some of which are life-threatening. Purpura results from trauma to blood vessels in the skin, causing hemorrhage into the surrounding tissue. Lesions are not blanched with pressure. Vessel damage can be the result of direct trauma, endothelial infection (e.g., rickettsial infection, meningococcemia), vessel occlusion, immune complex deposition, platelet depletion or dysfunction, or other conditions that cause vascular leakage of erythrocytes into the skin, mucous membranes, conjunctivae, or retina.

The clinical appearance of purpuric lesions depends on the size of the affected vessels, location of the vessels, extent of hemorrhage, and the coagulation status of the patient. Many noninfectious conditions can cause purpura. The morphology and other clinical findings may be useful in discriminating among likely causes. Purpuric lesions can be divided into six subtypes based on the size and morphology of the lesions: petechiae, macular purpura, ecchymoses, palpable purpura, noninflammatory retiform purpura, and inflammatory retiform purpura.[1]

Types of Purpuric Lesions and Pathogenesis

Petechiae, *macular purpura*, and *ecchymoses* are superficial, flat, cutaneous lesions that are 4 mm or smaller, 5 to 9 mm, and 1 cm or larger, respectively. *Palpable purpura* consists of raised, partially blanching, and erythematous to purple lesions, which typically are round. *Retiform purpura* has a lace-like pattern because the affected vessels are larger in the dermis and subcutis. *Inflammatory retiform purpura* initially is erythematous before evolving into purpura.

All purpuric lesions share similar changes in color based on the age of the lesion. They are initially bright red or deep red and become purple as the heme pigments break down and progress to green and yellow-brown before fading. The amount of time to fading depends on the amount of extravasated blood.

Petechiae, macular purpura, and ecchymoses are considered macular or flat purpura and result from simple extravasation of blood into the skin. Histologically, there is minimal inflammation, in contrast to the inflammatory hemorrhage seen in microvascular occlusion or cutaneous small-vessel vasculitis, which results in palpable purpura.[1] Inflammatory purpura results from occlusion by a clot with resulting ischemia and necrosis of the vessel. Vasculitis usually is caused by immune complexes deposited on the vessel lumen, which attracts neutrophils that destroy the complexes and injure the vessel wall. Retiform purpura and inflammatory retiform purpura result from occlusion and vasculitis, respectively, of larger, slow-flow vessels.

In patients with septicemia, purpura can arise from five main mechanisms: disseminated intravascular coagulation (DIC) and coagulopathy, direct vascular invasion and occlusion by organisms, infective vasculitis, emboli (e.g., in endocarditis), and vascular changes due to toxins.[2] Many infections are associated with thrombocytopenia with development of petechiae or ecchymoses, with or without DIC. Invasion of microorganisms into capillaries can occur especially with a bloodstream infection (BSI) due to *Neisseria meningitidis, Neisseria gonorrhoeae,* and *Pseudomonas aeruginosa* (Fig. 71.1). Diffuse vasculitis with pathologic evidence of rickettsiae in vascular endothelial cells is seen with Rocky Mountain spotted fever (RMSF) and epidemic typhus.

C
D

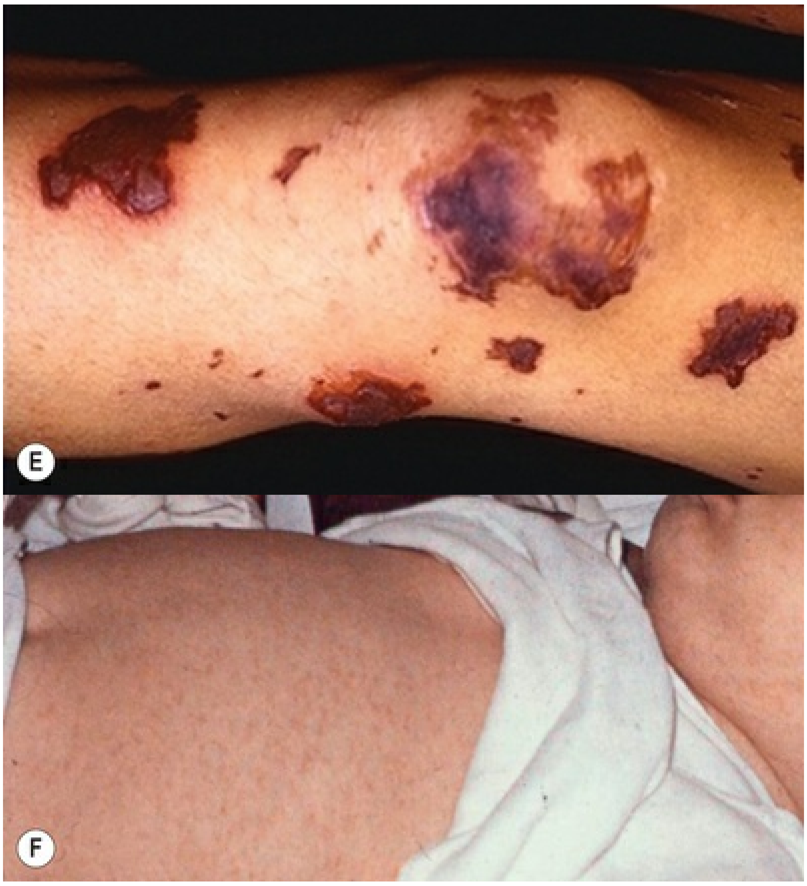

FIGURE 71.1 Skin manifestations of meningococcemia. The examination of one patient with this rapidly progressive disease found petechiae on the arm with exaggeration distal to the site of a tourniquet (A) and petechiae and purpura on the back (B). Another patient had a purpuric plaque on the distal leg (C), and purpuric lesions were seen around the knee in a patient at the time of admission (D) and 4 days later (E). Early manifestations of rapidly progressive, fatal meningococcemia include predominantly nonpetechial, macular lesions (F). (A, B, D, and E, courtesy of J.H. Brien, © C and F, courtesy of S.S. Long.)

Immune-mediated vasculitis is associated with a broad set of petechial rashes associated with atypical measles, hepatitis B, and chronic meningococcemia. Intravascular catheter–associated infections and acute and subacute endocarditis can manifest as infectious embolization complicated by infarction, tissue hemorrhage, and necrosis. Endocarditis also can be associated with immune-mediated vasculitis and petechiae. The scarlatiniform, sometimes petechial, eruptions of *Streptococcus pyogenes* (group A *Streptococcus* [GAS]) are an example of toxin-mediated rashes.

Causes of Purpura

Petechiae and Macular Purpura

Petechiae are small (≤4mm in diameter), nonblanching, purpuric macules that can appear on the skin, conjunctiva, retina, and mucous membranes. Lesions of macular purpura are larger than petechiae but smaller than ecchymoses. Both result from extravasation of blood from capillaries. In this chapter, the term *petechiae* is used to include all macular purpuric lesions smaller than 1 cm in diameter.

Petechiae typically resolve in 2 to 3 days but can evolve into ecchymoses, palpable purpura, vesicles, pustules, or necrotic ulcers, depending on the cause and clinical course. When petechiae occur on the nail bed, they appear as red-brown, longitudinal discolorations under the nail plate and are called *splinter hemorrhages*. In certain cases, they may be difficult to differentiate from telangiectases and angiomas. Because the latter lesions are not the result of extravasated blood, applying pressure with a glass slide to blanch the vessels (i.e., diascopy) can help differentiate petechiae from other vascular lesions.

The occurrence of petechiae in a febrile patient raises the concern for an infectious cause (Table 71.1). Petechiae can occur in crops, are commonly seen in BSIs, and usually occur with fever and as an early clinical sign of a BSI.[3] In contrast, petechiae can be seen in 10% to 32% of otherwise well-appearing infants receiving routine care in outpatient clinics.[4,5]

Rickettsia rickettsii (Rocky Mountain spotted fever)[a]	
Rickettsia typhi	

[a] Greater propensity of agent to cause purpura compared with other agents listed.

Historically, fever and petechiae in a child required evaluation for meningococcal infection. Early studies that focused on hospitalized children reported an incidence of meningococcal disease of 7% to 11% among children with fever and petechiae and a case-fatality rate of 10%.[6] In the past few decades in North America, bacterial causes of fever and petechiae have been relatively uncommon.[7,8] In a retrospective review of 129 hospitalized children with fever and petechiae, 20% had culture-proven bacterial infection, with 11% due to *N. meningitidis* and 6% due to *Haemophilus influenzae* type b.[9] Almost 60% of cases were attributed to viral causes.

A prospective study that included 190 children hospitalized with fever and petechiae documented 7% with meningococcal and 10% with GAS infection.[10] Children with invasive bacterial infections were more likely to appear ill, to have meningeal irritation, and to have petechiae below the nipple line.

Another prospective study attempted to capture a broader cohort of patients by evaluating 411 consecutive pediatric patients with fever and petechiae who were seeking care in a hospital emergency department.[3] Of the 53 ill-appearing patients (i.e., toxic appearance, inconsolable crying or screaming, or lethargy), 6 had invasive bacteremic infections, whereas none of the 357 well-appearing children had a positive blood culture or cerebrospinal fluid bacterial culture. In this study, only 2 patients had *N. meningitidis* (0.5%), 2 had *Streptococcus pneumoniae*, and 1 had GAS invasive infection. The study also found that a white blood cell count of 15,000 cells/mm^3 or higher was predictive of severe BSI.

A febrile patient with petechiae who appears well, has normal simple laboratory test results, has petechiae only above the nipple line, and has no nuchal rigidity has a low risk of invasive bacterial disease.[7] Petechiae in febrile patients most commonly is associated with viral infection because of the prevalence of viral infections and because viruses tend to damage small cutaneous vessels.[11]

Petechiae on the palate are characteristic of streptococcal pharyngitis[12] but also can be seen in Epstein-Barr virus infection, *Arcanobacterium haemolyticum* pharyngitis, rubella, roseola and viral hemorrhagic fevers, with thrombocytopenia, and following palatal trauma.[12] Oral hemorrhagic necrotic lesions have been attributed to *Actinomyces* infection.[13] Palmar and plantar petechiae can be seen in gloves and socks syndrome caused by parvovirus B19. In this condition, there is confluent erythema of the distal extremities with pinpoint macules evolving into petechiae on the palms and soles along with concurrent fever and leukopenia.[14]

Parvovirus also has been reported to cause a generalized petechial eruption[15] and petechiae in a bathing suit distribution.[16] Clusters of patients with generalized petechial eruptions are reported during community outbreaks of erythema infectiosum, and eruptions apparently are associated with the viremic phase of infection.[17]

Other infectious causes of generalized petechiae include scarlet fever, RMSF, parainfluenza, influenza, respiratory syncytial virus, enterovirus, rotavirus, atypical measles, rubella, dengue, and adenovirus.[8] For a patient with petechiae, fever, and recent travel to an endemic area, the clinician should consider epidemic and emerging infections such as Ebola and Chikungunya virus infections[18] and rare causes such as Brazilian purpuric fever,[19] Zika virus,[20] and severe fever with thrombocytopenia syndrome.[21]

Petechiae or purpura can have noninfectious causes such as drug reactions, acute leukemia,[8] low platelet counts, and mechanical causes (Table 71.2). Severe coughing or vomiting can increase intrathoracic pressure, causing petechiae in areas perfused by the superior vena cava and approximately corresponding to skin areas above the nipple line. This distribution of petechiae is not always benign; 25% of patients with fever and petechiae confined to the upper torso had bacterial infection in one study.[9] Petechiae can form distal to placement of a tourniquet and have no clinical significance without other findings. In contrast, the tourniquet test can cause distal petechiae in patients with dengue fever and is positive in most patients with dengue hemorrhagic fever.[22]

TABLE 71.2

Major Noninfectious Causes of True Purpura and Purpura Mimics

True Purpura	Purpura Mimics
PLATELET DISORDERS	**NEONATES**
Thrombocytopenia Decreased production of platelets	**Extramedullary Hematopoiesis (“Blueberry Muffin” Lesions)**
• Drug induced	Congenital infections
• Bone marrow infiltration or aplasia	Aicardi-Goutières syndrome
• Toxin induced	Rh hemolytic disease of the newborn
Decreased survival of platelets	Spherocytosis
• Disseminated intravascular coagulation	Twin-twin transfusion
• Drug induced	Myofibromatosis
• Hemolytic-uremic syndrome	Self-healing reticulohistiocytosis
• Idiopathic and autoimmune thrombocytopenic purpura	Metastatic malignant tumors • Langerhans cell histiocytosis
• Prosthetic heart valve	• Congenital leukemia
• Hypersplenism	• Neuroblastoma
• Sequestration	• Rhabdomyosarcoma • Rhabdomyosarcoma
Platelet Dysfunction	**Neonatal Lupus**
Thrombocytosis	**Phototherapy-Induced Purpura**
VASCULAR DISORDERS	**Subcutaneous Fat Necrosis**
Noninflammatory Purpura	**Vascular Lesions**
Cushing disease	Congenital hemangioma
Corticosteroid therapy	Congenital glomuvenous malformation
Ehlers-Danlos syndrome	Venous malformation
Fat embolism	Tufted angioma
Increased capillary pressure (e.g., vomiting, posttussive)	**CHILDREN** Angiokeratoma corporis diffusum
Scurvy	Arthropod bites
Trauma or child abuse	Blue rubber bleb nevus syndrome
Vasculitis and Inflammatory Purpura	Diffuse reticulate purpura in anorexia nervosa
• Brown recluse spider bite	Erythema multiforme
• Churg-Strauss syndrome	Hemorrhagic urticaria multiforme
• Dermatomyositis	Multifocal lymphangiomatosis with thrombocytopenia
• Drug- or toxin-induced hypersensitivity	
• Dysproteinemias	Pityriasis lichenoides
• Graft-versus-host disease	Pityriasis rosea
• Henoch-Schönlein purpura	After EMLA cream (i.e., lidocaine and prilocaine) application
• Inflammatory bowel disease	
• Malignant atrophic papulosis	Psychogenic purpura
• Pernio (i.e., chilblains)	Sarcoidosis
• Polyarteritis nodosa	
• Pyoderma gangrenosum	
• Pigmented purpura	
• Rheumatoid arthritis	
• Scleroderma	
• Serum sickness syndrome	
• Sjögren syndrome	
• Sweet syndrome (i.e., acute febrile neutrophilic dermatosis)	
• Systemic lupus erythematosus	
• Urticarial vasculitis	
• Wegener granulomatosis	
COAGULATION DISORDERS	
Clotting Factor Deficiencies	

Increased use or proteolysis	
Inadequate production	
Presence of inhibitor of coagulation	
Synthesis of abnormal clotting factor	
Thrombotic Disorders	
Antiphospholipid syndrome	
Antithrombin III deficiency	
Plasminogen deficiency	
Protein C deficiency	
Protein S deficiency	

In newborns, petechiae can occur at sites of pressure during delivery through the birth canal, but petechiae also can result from acquired infection or maternal antiplatelet antibodies, and appropriate evaluation should be performed. Older children with petechiae without fever should be evaluated for blood dyscrasias. Petechial eruptions can occur in the setting of thrombocytopenia due to hematologic malignancy or chemotherapeutic agents, and exanthems can be associated with viral infections or drug eruptions. Careful evaluation of the history, symptom complex, and laboratory evaluation is required, and a skin biopsy may be necessary.

Ecchymoses

Ecchymoses (i.e., bruises) are purpuric, flat patches on the skin. Typically, ecchymoses are 1 cm or larger in diameter and are caused by a greater volume of extravasated blood than occurs with petechiae. Ecchymoses tend to take longer to resolve (1–3 weeks). Petechiae in a patient with an underlying coagulopathy can quickly evolve into ecchymoses.

Ecchymoses resulting from infection are uncommon in children. When ecchymoses occur, they are most frequently caused by *N. meningitidis* septicemia with coagulopathy.[23] Other causes include other gram-negative bacteria, gram-positive bacteria (e.g., *Staphylococcus aureus*, GAS, and *S. pneumoniae*), viruses (e.g., viral hemorrhagic fevers), and *Rickettsia rickettsii* (RMSF).[23–26]

In the neonate, ecchymoses at sites of cutaneous trauma (e.g., medical tape, intravenous catheter, arm board, monitor lead) can be caused by inoculation of molds and other opportunistic pathogens into the skin. Urgent evaluation and empiric treatment are critical as hematogenous spread can occur rapidly.[27]

Ecchymosis occurring acutely and in an ill-appearing patient is called *purpura fulminans*. In this setting, ecchymoses evolve rapidly, usually are symmetric in distribution, and evolve into necrotic patches with eschars.[3] Purpura fulminans is caused by abnormalities in coagulation due to infection. Most commonly, this occurs in the setting of acute infection such as caused by *N. meningitidis*, gram-negative bacilli, or overwhelming infection due to a variety of organisms in a compromised host, especially neutropenic or asplenic patients.[23] Purpura can occur 7 to 10 days after an otherwise benign infection (i.e., idiopathic purpura fulminans). Idiopathic purpura fulminans has been associated with varicella, scarlet fever, streptococcal tonsillopharyngitis, viral exanthems, rubella, measles, upper respiratory tract infections, and gastroenteritis.[23]

A variant of purpura fulminans called *symmetric peripheral gangrene* results in ischemic necrosis of the distal parts of two or more extremities without large-vessel obstruction. This variant is associated with higher mortality and morbidity (e.g., amputation) rates.[28] Purpura fulminans and symmetric peripheral gangrene occur more frequently in infants and children than in older individuals.[2] In neonates, purpura fulminans can be a manifestation of inherited homozygous protein C deficiency or rarely of protein S deficiency. BSIs in older children with these underlying deficiencies (and properdin deficiency, splenic dysfunction, or neutropenia) can lead to purpura fulminans.

Palpable Purpura

Unlike petechiae and ecchymoses, palpable purpura is a condition in which raised, purpuric papules and plaques can range from a few millimeters to a few centimeters in diameter. Palpable purpura favors dependent areas such as the lower extremities, but in the supine patient, lesions can occur on the back, buttocks, and distal arms. Palpable purpura can evolve into nodular, vesicular, pustular, necrotic, or ulcerative lesions.

Palpable purpura classically is associated with leukocytoclastic vasculitis, an inflammatory process that injures the vessel.[29] Histopathologically, fibrin deposition in vessel walls, neutrophilic debris, and perivascular lymphocytes are seen. Palpable purpura also can occur with *S. aureus* BSI or in bacterial endocarditis as the result of infectious microemboli occluding the vascular lumen. Osler nodes and Janeway lesions found in bacterial endocarditis are types of microembolism-induced palpable purpura. Osler nodes are tender nodules that are seen on the palms, soles, and pads of the fingers and toes. Janeway lesions are nontender, purpuric macules, papules, or nodules usually found on the palms and soles. Lesions similar to Osler nodes have been reported in typhoid fever, polyarteritis nodosa, systemic lupus erythematosus, Churg-Strauss syndrome, mixed cryoglobulinemia, and Wegener granulomatosis.[1,2]

Palpable purpura has a variety of causes, including infection (10%–15%), drug reactions, immunization, and autoimmune disease. The most common infectious causes include *N. meningitidis*, *S. aureus*, and *N. gonorrhoeae,* but it also has been caused by *Mycobacterium*, *Rickettsiae*, and *Mycoplasma* spp., and rarely by *Bartonella*, *Salmonella*, *Campylobacter*, *Yersinia*, *Brucella* spp, and *Treponema pallidum*. Viral causes include hepatitis viruses (i.e., hepatitis C is more common than hepatitis B, and hepatitis B is more common than hepatitis A), hepatitis virus vaccine, and infection due to human immunodeficiency virus (HIV), parvovirus, and rarely by cytomegalovirus, varicella, and influenza.[1]

Noninfectious causes of palpable purpura in the pediatric population include Henoch-Schönlein purpura (HSP), which is the most common vasculitis seen in childhood, and acute hemorrhagic edema of infancy (AHEI). Palpable purpura is the presenting sign in almost 50% of cases with HSP. Diagnostic criteria for HSP include palpable purpura (with lower limb predominance), a mandatory criterion, along with at least one of the following: diffuse abdominal pain, tissue biopsy showing predominant IgA deposition, acute arthritis or arthralgia of any joint, and renal involvement.[30] If the distribution of cutaneous lesions is atypical, biopsy confirming IgA deposition is required. Hemorrhagic bullae also have been reported in HSP, and their presence does not appear to affect prognosis.[31]

HSP is most common between the ages of 5 and 10 years, and AHEI usually manifests in children younger than 2 years of age.[32] Some consider AHEI a distinct entity, whereas others consider it infantile HSP. AHEI typically manifests with fever, edema, and rosette-shaped, purpuric cutaneous lesions favoring the face, ears, and limbs. AHEI has a benign course, resolving over 3 weeks without sequelae, and it lacks visceral involvement.[33]

Retiform Purpura

Retiform purpura results from occlusion of dermal and subcutaneous vessels, which causes a lace-like pattern of purpura. A complete reticulate pattern is not usually seen, but rather a puzzle piece–like or branching pattern occurs because of the angulated or sometimes serpentine pattern of the purpura. Vascular invasion by fungi (e.g., *Mucor*, *Aspergillus* in immunocompromised patients), gram-negative organisms (e.g., *Pseudomonas*) that multiply in arterioles, and *Strongyloides* can cause noninflammatory retiform purpura, whereas vasculitis during BSI can cause inflammatory retiform purpura.[1]

Urticaria and Erythema Multiforme

Kara N. Shah

Urticaria and erythema multiforme (EM) are common cutaneous hypersensitivity reactions seen in children. They can be triggered by infection, although noninfectious causes also are prevalent. Although they are distinctly different entities, acute urticaria often is misdiagnosed as EM. Although urticaria usually is an isolated finding, urticaria and urticarial dermatoses can be seen in several syndromes and disorders such as papular urticaria, urticarial vasculitis, and the cryopyrin-associated periodic syndromes (CAPSs).

Some terminology has changed. The use of the historical and confusing terms, such as EM minor to refer to classic EM and EM major to refer to Stevens-Johnson syndrome, has been abandoned.

Urticaria

Etiologic Agents

Acute and chronic forms of urticaria have been attributed to numerous bacterial, viral, fungal, and other infectious agents (Box 72.1). Noninfectious causes and associations include foods, medications, physical stimuli, aeroallergens, and systemic diseases (Box 72.2).[1] In infants younger than 6 months, urticaria largely is caused by a cow's milk allergy, and in older infants, food allergy, infection (particularly viral), and medications predominate.[2–4]

[a] Most common.

[b] Can cause a pseudoallergic reaction.

In acute urticaria in children, an infectious cause can be demonstrated in up to 60% of cases.[3,5,6] Viral upper respiratory tract and gastrointestinal tract infections are the primary infectious triggers of acute urticaria in children, with rhinovirus, adenovirus, rotavirus, and *Streptococcus pyogenes* the most commonly associated infectious agents.[6,7]

Most cases of chronic urticaria in children have idiopathic, autoimmune, or physical causes.[8–13] Physical urticaria is the most commonly identified cause. Triggers include cold exposure, pressure, heat, exercise, vibration, and water.[11] Chronic urticaria can be associated with a variety of infections.[3,9,12–15] The relevance of occult dental, sinus, or ear infections remains controversial.[16] In one study of adults and children with chronic urticaria evaluated at an academic medical center in Turkey, 10 (31.2%) of 32 of children with chronic urticaria tested positive for *Helicobacter pylori* antigen in their stool, and urticaria resolved after eradication of *H. pylori*.[17] However, based on the lack of resolution of most cases of chronic urticaria after treatment of the purported infectious trigger, some experts argue that there is no relationship between chronic infection and chronic urticaria.[18] Some evidence suggests that patients with chronic autoimmune urticaria may manifest an infection-associated autoreactive response.[19] There is no demonstrated association between chronic urticaria and malignancy.[20]

Epidemiology

Urticaria is a common problem over a lifetime, occurring in 20% to 25% of the population.[21,22] For children and adolescents, prevalence estimates range from 2% to 20%.[3,23–25] There is no known sex, ethnic, or racial predisposition. Most pediatric cases of urticaria are acute and self-limited. In children, chronic urticaria is uncommon, with a prevalence of only 0.1% to 0.3%.[26] Controversy exists about whether there is an increased prevalence of urticaria among people with a personal or family history of atopic disease, although a prospective birth cohort study from Germany demonstrated a significant association between the cumulative prevalence of urticaria at age 10 years and allergic sensitization with peanut, soy, and wheat but not with aeroallergens. A personal history of asthma, eczema, and seasonal allergies and parental history of atopy or urticaria also were strongly associated.[25] A history of atopy has been associated with increased severity and duration of acute urticaria in children.[27,28]

Pathogenesis and Pathologic Findings

Urticaria results from degranulation of mast cells and basophils, which release of histamine and other vasoactive mediators.[29] Histamine acts through H_1 and H_2 receptors to produce vasodilation and altered vascular permeability that result in fluid extravasation and dermal edema, forming urticarial lesions. Together with the axonal reflex, which produces the associated cutaneous flare, these features comprise the triple response of Lewis. Intense pruritus also can result from histamine released into the dermis. Other mediators of urticaria include kinins, prostaglandins, leukotrienes, cytokines, chemokines, and neuropeptides.

Urticaria can be immunologic or nonimmunologic. Immune-mediated urticaria results from an immunoglobulin E (IgE)–mediated type I hypersensitivity reaction; from the development of IgG autoantibodies against IgE or the high-affinity IgE FceRI or FceRII receptor (i.e., type II hypersensitivity reaction); from the binding of circulating immune complexes to mast cells expressing Fc receptors for IgG and IgM (i.e., type III hypersensitivity reaction); and rarely from T-lymphocyte–mediated activation of mast cells (i.e., type IV hypersensitivity reaction).[29]

In nonimmunologic (pseudoallergic) urticaria, direct degranulation of mast cells and basophils occurs in response to exogenous factors such as pressure and cold; from activation of membrane receptors involved in innate immunity (e.g., by opioids); through direct mast cell toxicity, as occurs with iodinated radiographic contrast agents, drugs (e.g., aspirin, nonsteroidal anti-inflammatory drugs [NSAIDs]), and foods; or through inhibition of kinin breakdown by inhibitors of angiotensin-converting enzymes.

Urticaria due to infectious agents is postulated to involve the formation of immune complexes with activation of complement and release of anaphylatoxins or development of IgE antibodies to microbial antigens.[30,31] There is no reported difference in total serum IgE level, peripheral blood eosinophil count, or IgE-mediated sensitization to aeroallergens in children with acute or chronic urticaria, although aeroallergen sensitization is high in both groups.[32]

Clinical Manifestations, Differential Diagnosis, and Approach

Commonly referred to as *hives* or *welts*, urticaria is characterized by the appearance of wheals with or without angioedema. Almost all cases of urticaria in infants and most cases in children are acute and resolve within 6 weeks. Chronic urticaria is diagnosed when urticaria occurs daily or almost daily, with or without angioedema, for more than 6 weeks.

Hallmark clinical features of urticaria include the acute onset of edematous papules and plaques, which often manifest with central clearing; are surrounded by erythema; pruritus, or a burning sensation; and have an evanescent duration of 1 to 24 hours.[14] The size of individual wheals can vary from a few millimeters to several centimeters in diameter. Although classically annular or circular, wheals can assume a bizarre, serpiginous morphology (Fig. 72.1). Occasionally, wheals can have a transient, dusky, violaceous center, which can be confused with EM; this variant of acute urticaria has been referred to as *urticaria multiforme* or *acute annular urticaria*.[33,34] Associated dermatographism, a form of pressure-induced urticaria, often is seen.

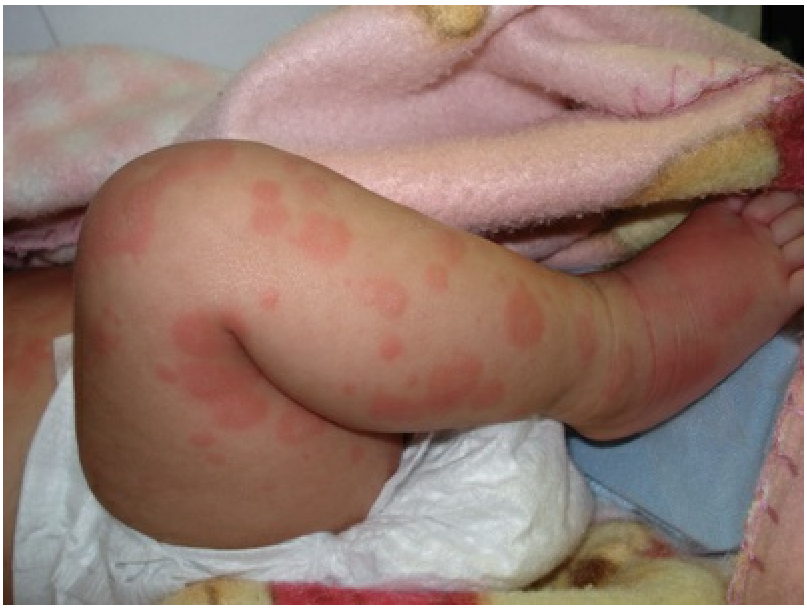

FIGURE 72.1 Acute urticaria. Migratory, edematous, erythematous plaques with central clearing are associated with edema of the hands and feet.

Angioedema, defined by edema of the deep dermis and subcutis that classically involves the mucous membranes and acral areas (i.e., hands, feet, and face), occurs in about 5% to 10% of children with urticaria. Angioedema usually resolves more slowly that urticaria and can last for up to 72 hours. Patients can have a burning or stinging sensation, but pruritus usually is not prominent.

When urticaria is associated with anaphylaxis, systemic symptoms develop as a result of the release of vasoactive mediators, and swelling of viscera can occur. Systemic symptoms and signs include hoarseness, respiratory distress, emesis, diarrhea, abdominal pain, arthralgia, flushing, syncope, hypotension, and cardiovascular collapse.

The clinical approach to urticaria in children involves establishing a definitive diagnosis of spontaneous urticaria and identifying a plausible trigger, both of which in most cases is established by a thorough and pertinent history and physical examination. The history should focus on the frequency and duration of wheals; associated symptoms such as pruritus or burning; systemic symptoms such as fever, arthralgia, or respiratory or gastrointestinal symptoms; and recent medication exposures.

The physical examination should focus on the morphology, distribution, and progression of wheals, and their transient nature can be documented through serial examinations, with marking of individual wheals if necessary. Angioedema, mucous membrane abnormalities, and specific findings such as lymphadenopathy, hepatosplenomegaly, and arthritis should be identified. The differential diagnosis of urticaria includes other annular erythemas, such as EM; autoinflammatory syndromes, particularly CAPSs; exanthematous drug eruptions; and urticarial eruptions associated with systemic disease, such as systemic lupus erythematosus and juvenile idiopathic arthritis[35] (see Box 72.2).

Laboratory Findings and Diagnosis

Skin biopsy can be helpful in equivocal cases or when a diagnosis other than urticaria (e.g., urticarial vasculitis) is suspected. Histologically, urticaria demonstrates dermal edema, dilation of postcapillary venules and lymphatic vessels, and a sparse, mixed perivascular infiltrate with various numbers of eosinophils and neutrophils. An increase in mast cells also may be seen.[36] In some cases, the histology of urticaria can be nonspecific or appear as normal skin.

Diagnostic tests are recommended when the history and physical examination suggest a specific, treatable cause (e.g., streptococcal pharyngitis, bacterial enteritis, food allergy) or when the diagnosis is uncertain or unlikely to be urticaria. For mild, chronic urticaria under pharmacologic control and in the absence of corroborating physical examination findings or a suggestive history, extensive laboratory evaluations usually are not indicated.[37]

Skin prick testing combined with ImmunoCAP testing as clinically indicated can be performed if food or environmental allergy is suspected to be the cause. Oral food challenges and elimination diets, if clinically indicated, should be performed under the guidance of an experienced allergist. Provocation testing may be performed to validate a diagnosis of physical urticaria.

If a specific infectious cause is suspected, directed serologic or microbiologic testing should be performed, if indicated. Additional laboratory evaluations considered in selected cases of urticaria in which the history and physical examination suggest systemic disease include a complete blood cell count with a differential leukocyte count, erythrocyte sedimentation rate (ESR), thyroid function tests, and levels of C-reactive protein, serum hepatic enzymes, antinuclear antibodies, tryptase, immunoglobulins, and complement (e.g., C3, C4, CH50). The basophil histamine release assay is a specialized diagnostic test that can be used to confirm a diagnosis of chronic autoimmune urticaria by detecting IgG antibodies to FcεRI, FcεRII, or IgE or an alternate histamine releasing factor. Imaging studies such as chest or sinus radiography are considered for selected patients.

Management

Primary management focuses on providing symptomatic relief and eliminating or avoiding the known causes or triggers.[38] Factors that can aggravate urticaria include heat, exercise, emotional stress, and medications such as aspirin and NSAIDs.[39] Infection should be treated if indicated, although treatment of the associated infection results in improvement of urticaria in only a minority of patients.

The most successful approach to treating the symptoms of urticaria is with medications that block the effect of histamine at the level of its receptor on cutaneous blood vessels. Antihistamines that block H_1 receptors are considered as first-line therapy for urticaria.[38] Hydroxyzine hydrochloride is the most effective of the classic H_1 antihistamines for suppression of the wheal-and-flare response, pruritus, and dermatographism.[40–42]

Because of significant sedative and anticholinergic effects of the first-generation antihistamines, newer nonsedating H_1 antihistamines such as fexofenadine, loratadine, and cetirizine are recommended as first-line therapeutic agents. These agents are as efficacious as first-generation antihistamines and have a longer duration of action. Levocetirizine is safe and effective in reducing the duration of acute urticaria in infants as young as 12 months of age.[43]

Antihistamine therapy should be initiated at the upper end of the recommended dosage range and then gradually increased as needed until symptoms are relieved or until side effects, particularly sedation, become prohibitive. Use of antihistamines at two to four times the recommended dosage by the manufacturer may be required.[44] Administering most of the daily dose just before bedtime can minimize daytime sedation. Alternative or adjunctive therapies should be considered in patients who do not respond to H_1 antihistamines.[38] The therapeutic response to the H_1 antihistamines can be improved with the addition of an H_2 receptor antagonist such as cimetidine or ranitidine.[45] H_2 receptor antagonists should not be used as monotherapy because of their insufficient H_1 blockade.

Topical corticosteroids are of limited utility in the treatment of urticaria. Use of systemic corticosteroids rarely is indicated in children and discouraged for prolonged use in cases of chronic urticaria due to concerns about significant adverse effects. A short course of oral corticosteroids usually is reserved for children with severe, unremitting symptoms, especially asthma, laryngeal edema, or anaphylaxis, or when angioedema on the face is particularly severe.

Rarely, chronic urticaria is severe enough that despite the use of oral antihistamines, additional systemic therapy is warranted. Alternative or adjunctive therapies include mast cell stabilizers, leukotriene antagonists, tricyclic antidepressants (especially doxepin), dapsone, cyclosporine, mycophenolate mofetil, and omalizumab.[44,46]

Complications and Prognosis

Complications are rare but can result from associated angioedema or anaphylaxis. Most cases of acute urticaria resolve within 1 to 2 weeks, with or without therapy. Approximately one half of cases of chronic urticaria resolve within 6 months, and one half resolve within 1 to 3 years.[3,9,47] Patients with associated angioedema are more likely to have persistent urticaria.[48]

Erythema Multiforme

Etiologic Agents and Epidemiology

Although numerous infections have been reported in association with EM, herpes simplex virus (HSV) is by far the most common and best documented (Box 72.3)[49,50] Recurrent EM is significantly associated with HSV infection.[51,52] Unusual presentations of EM include neonatal disease due to congenital cytomegalovirus infection and recent hepatitis B and bacille Calmette-Guérin (BCG) vaccination; idiopathic neonatal EM also has been reported.[53–55] EM is associated rarely with Kawasaki disease.[56–58] Persistent EM has been associated with Epstein-Barr virus (EBV) infection, inflammatory bowel disease, and malignancy.[59]

[a] Most clearly established.

Epidemiologic data on EM in children are lacking. Typically, a disease of adults 20 to 40 years of age, an estimated 20% of cases are seen in children and adolescents.[60–62] There is no clear sex, ethnic, or racial predisposition. Recurrent EM occurs more commonly in the spring.[62] Human leukocyte antigens B62, B35, and DR53 have been associated with a higher risk of HSV-induced EM, particularly recurrent EM.[63]

Pathogenesis and Pathologic Findings

The pathogenesis of EM is incompletely understood, but evidence increasingly implicates a host-specific, cell-mediated immune response to an antigenic stimulus that targets keratinocytes at the dermal-epidermal junction.[61,62] Cytokines released by activated mononuclear cells and keratinocytes contribute to necrosis of keratinocytes. Although circulating and tissue-bound immune complexes can be demonstrated, they do not appear to play a central role in pathogenesis. HSV antigens and DNA have been documented in skin lesions from patients with EM and are absent in unaffected skin of patients.[50,64–66]

Histologically, EM demonstrates mild spongiosis, lymphocytic exocytosis, variable papillary dermal edema, a perivascular and interstitial mononuclear infiltrate, and basal vacuolization with liquefactive degeneration of the basal layer of the epidermis; the feature of satellite cell necrosis is a hallmark of EM.[36] An increased number of eosinophils or nuclear dust, or both, can be seen. Subepidermal blisters and necrosis of the entire epidermis can be seen in more severe cases.

Clinical Manifestations, Differential Diagnosis, and Clinical Approach

EM has various cutaneous manifestations. EM is characterized by the acute onset of a symmetric, fixed cutaneous eruption of erythematous macules, papules, vesicles, and bullae, which most commonly are distributed on the palms, dorsal surfaces of the hands and feet, and extensor surfaces of the arms and legs, with relative sparing of the face, trunk, and mucous membranes.[61]

Lesions can expand and evolve over several days to assume the classic annular target appearance with a dusky, necrotic center surrounded by a ring of edema and pallor and an erythematous border (Fig. 72.2). The development of new lesions 72 hours after onset is unusual. The isomorphic phenomenon, which refers to the development of lesions at sites of prior skin trauma, is common. Lesions usually are asymptomatic, although patients can have a burning sensation or pruritus. Photoaccentuation is common.

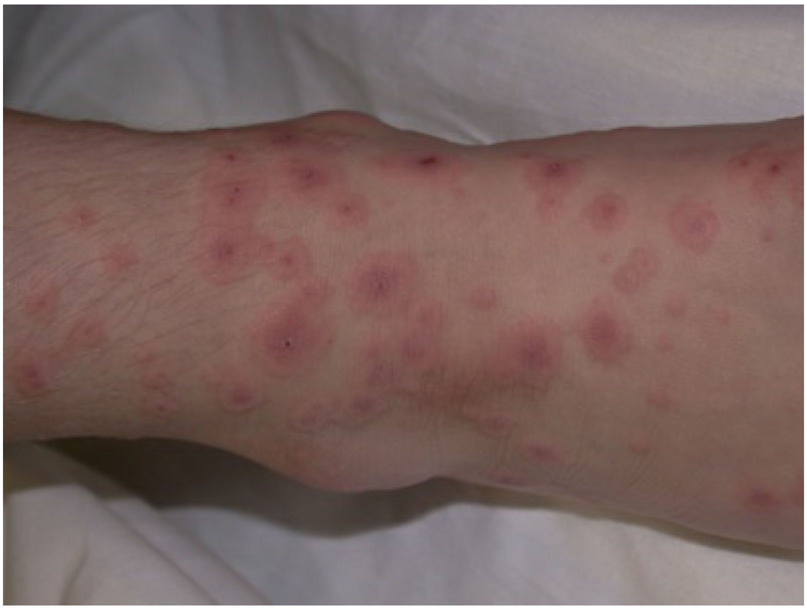

FIGURE 72.2 Erythema multiforme. Target lesions manifest as edematous papules with dusky, necrotic centers and erythematous, annular borders.

Prodromal symptoms usually are absent, although low-grade fever, malaise, and upper respiratory tract symptoms can occur. Cervical lymphadenopathy can be associated with oral involvement, which occurs in about 25% of cases and usually includes localized erosions involving the gingival, tongue, or buccal mucosa (Fig. 72.3). Rarely, more extensive involvement can be seen, but extensive hemorrhagic erosions and crusting such as is seen with Stevens-Johnson syndrome does not occur.[61,62] Ocular or other mucous membrane involvement does not occur and, if present, should raise the possibility of Stevens-Johnson syndrome (see Chapter 70).

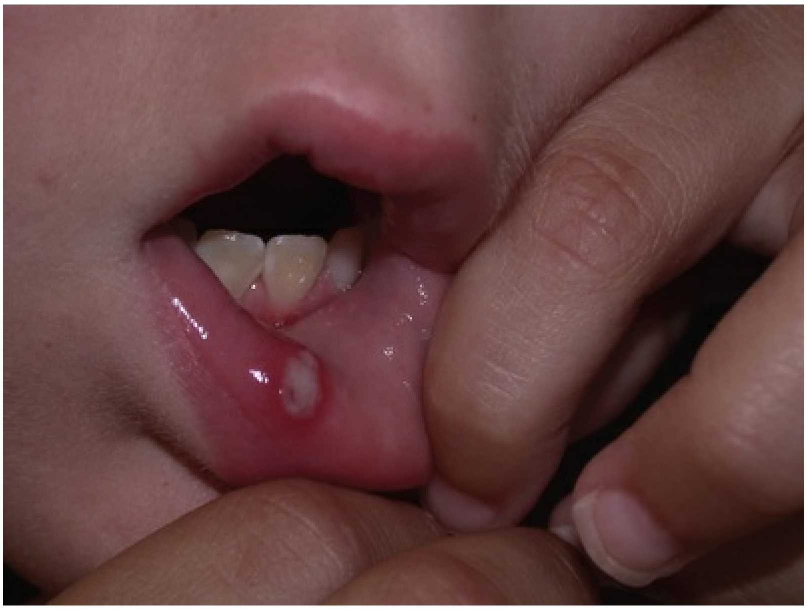

FIGURE 72.3 Oral aphthae in a child with herpes simplex virus (HSV)–associated recurrent erythema multiforme.

Lesions of HSV-induced recurrent EM typically develop 10 to 14 days after the onset of recurrent mucocutaneous lesions (usually oral mucosa) or occur after asymptomatic reactivation of HSV.[67] EM has a similar morphology and distribution from episode to episode, but it can vary considerably in frequency and duration in a given patient.

The differential diagnosis includes acute urticaria, vasculitis, viral exanthem, exanthematous drug eruption, fixed drug eruption, Stevens-Johnson syndrome, acute hemorrhagic edema of infancy, neutrophilic dermatosis, and polymorphous light eruption. An EM-like allergic contact dermatitis can be seen after exposure to agents such as *p*-phenylenediamine in hair dyes and topical triamcinolone.[68–71]

Laboratory Findings and Diagnosis

Although typically a clinical diagnosis, skin biopsy can help to confirm the diagnosis. There are no typical laboratory abnormalities, although elevated an ESR, moderate leukocytosis, and mildly elevated levels of serum hepatic transaminases can be seen in some patients. In cases when HSV infection is suspected, polymerase chain reaction (PCR) or direct fluorescent antigen (DFA) testing can be performed on specimens from primary or recurrent cutaneous lesions.[72]

Management

Supportive treatment is all that is necessary in most cases. Use of antihistamines (orally) and analgesics (orally and topically for oral mucosal involvement) may be helpful in addressing associated pruritus and pain, respectively. Debridement of necrotic skin is not recommended, and blisters should be left intact when possible. Areas that have eroded, blistered, or crusted should be monitored for infection. Re-epithelialization of denuded areas is facilitated by application of bland emollients, antibiotic ointments, or use of petrolatum-impregnated gauze or hydrocolloid or foam dressings. No controlled, prospective study supports the use of corticosteroids.[62,73] Oral acyclovir given early for episodes of primary or recurrent EM may lessen the severity of the clinical course.[67,74] Use of famciclovir for the management of recurrent herpes-associated EM has been reported in a few adults.[75]

Complications, Prognosis, Sequelae, and Prevention

Complications are unusual, but secondary bacterial skin infections can occur. EM typically resolves within 2 to 4 weeks. Significant postinflammatory hyperpigmentation can result, but scarring is unusual unless secondary bacterial infection of the skin has occurred. Recurrent EM usually remits after several years.

Preventive measures for recurrent EM include sun-protective measures such as routine use of sunscreen, use of protective clothing, and avoidance of excess exposure. Use of acyclovir or valacyclovir (in adolescents older than 12 years) for 6 to 12 months can be considered at suppressive doses for children and adolescents with more than three to four recurrences per year (see Chapter 204).

Papules, Nodules, and Ulcers

Jennifer L. Sorrell, Christine T. Lauren

Papules, nodules, and ulcers are primary lesions of the skin with a variety of infectious and noninfectious causes (Tables 73.1 and 73.2). A *papule* is a raised superficial lesion that is less than 1 cm in diameter whose surface may be smooth, scaly, or hyperkeratotic. A larger (>1 cm), raised, and often flatter-topped lesion is called a *plaque.* A *nodule* is a solid, palpable lesion that is larger than 1 cm in diameter. An *ulcer* is a loss of skin to the level of the dermis or deeper. An *erosion* is shallower, and the loss of skin is limited to the epidermis.

TABLE 73.1

Primary Infectious Causes of Papules, Nodules, and Ulcers

Disease Entity	Skin Lesions	Infectious Agent
ARTHROPODS		
Cutaneous myiasis	P, N	*Dermatobia hominis*
Scabies	P	*Sarcoptes scabiei*
Tungiasis	P	*Tunga penetrans*
BACTERIA		
Actinomycosis	P, N, U	*Actinomyces israelii*
Anthrax	P, U	*Bacillus anthracis*
Bartonellosis	P, N	*Bartonella bacilliformis*
Brucellosis	P, N	*Brucella* spp.
Cat scratch disease	P, N	*Bartonella henselae*
Chancroid	P, U	*Haemophilus ducreyi*
Diphtheria	P, U	*Corynebacterium diphtheriae*
Ecthyma	U	*Streptococcus pyogenes*

Ecthyma gangrenosum	P, U	*Pseudomonas aeruginosa*
Folliculitis	P	*Enterobacter* spp.
	P	*Escherichia coli*
	P	*Klebsiella* spp.
	P, N	*Proteus* spp.
	P	*Pseudomonas aeruginosa*
	P	*Staphylococcus aureus*
Furunculosis, carbunculosis	N	*Staphylococcus aureus*
Granuloma inguinale	P, N, U	*Calymmatobacterium granulomatis*
Hidradenitis suppurativa	N	Mixed skin flora
Impetigo	P, U	*Staphylococcus aureus*
	P, U	*Streptococcus pyogenes*
Lyme disease	P, U	*Borrelia burgdorferi*
Lymphogranuloma venereum	P, U	*Chlamydia trachomatis*
Malakoplakia	P, N, U	Multiple organisms
Melioidosis	N, U	*Pseudomonas pseudomallei*
Meningococcemia, chronic	P	*Neisseria meningitidis*
Nocardiosis	P, N	*Nocardia brasiliensis*
	P, N	*Nocardia asteroides*
Pyomyositis	N	Multiple organisms
Rhinoscleroma	N, U	*Klebsiella rhinoscleromatis*
Sycosis barbae	P	*Staphylococcus aureus*
Septic emboli	P, U	Multiple organisms
Tularemia	U	*Francisella tularensis*
FUNGI		
Blastomycosis	P, N, U	*Blastomyces dermatitidis*
Candidiasis	P, N, U	*Candida albicans*
	P, N, U	*Candida tropicalis*
Coccidiomycosis	P, N, U	*Coccidioides immitis*
Cryptococcosis	P, N, U	*Cryptococcus neoformans*
Folliculitis	P	*Candida albicans*
	P	*Malassezia furfur*
Histoplasmosis	P, N, U	*Histoplasmosis capsulatum*
Hyalohyphomycosis	N	Multiple organisms
Mycetoma	P, N, U	Multiple organisms
Phaeohyphomycosis	N	Multiple organisms
Sporotrichosis	P, N, U	*Sporothrix schenckii*
Tinea barbae, tinea capitis	P, N	*Trichophyton* spp.
	P, N	*Microsporum* spp.
Tinea corporis	P	*Trichophyton* spp.
	P	*Microsporum canis*
Zygomycosis	U	*Absidia, Rhizopus, Mucor*
HELMINTHS		
Dracunculosis (guinea worm)	U	*Dracunculus medinensis*
Larva currens	P	*Strongyloides stercoralis*
Cutaneous larva migrans	P	*Ancylostoma braziliense*
	P	*Ancylostoma caninum*
Cysticercosis	N	*Taenia solium*
Ground itch	P	*Necator americanus*
Loiasis	N	*Loa loa*
Ancylostoma duodenale		
Onchocerciasis	P, N	
Onchocerca volvulus		
Cercarial dermatitis	P	
Trichobilharzia spp.		

Schistosomiasis	P	
Schistosoma spp.		
MYCOBACTERIA		
Nontuberculous mycobacteriosis	P, N, U	*Mycobacterium marinum*
	N, U	*Mycobacterium kansasii*
	N, U	*Mycobacterium scrofulaceum*
	N, U	*Mycobacterium ulcerans*
	P, N, U	*Mycobacterium avium* complex
	P, N, U	*Mycobacterium fortuitum, M. chelonae*
	P, N, U	*Mycobacterium leprae*
Cutaneous tuberculosis	P, N, U	*Mycobacterium tuberculosis*
	P, N, U	*Mycobacterium bovis*
	P, N, U	Bacille Calmette-Guérin
PROTOZOA		
Amebiasis	N, U	*Entamoeba histolytica*
Leishmaniasis	P, N, U	*Leishmania* spp.
TREPONEMES		
Pinta	P	*Treponema carateum*
Syphilis	P, N, U	*Treponema pallidum*
Yaws	P, N, U	*Treponema pertenue*
VIRUSES		
Epidermodysplasia verruciformis	P	Human papillomaviruses
Herpes simplex	N, U	Human herpes virus types 1 and 2
Herpes zoster	N, U	Varicella-zoster virus (HHV-3)
Milker nodule	P, N	Paravaccinia virus
Molluscum contagiosum	P, N	Molluscum contagiosum virus
Orf	P, N	Orf virus
Parvovirus	P	Parvovirus B19
Warts	P, N	Human papillomaviruses

N, nodule; P, papule; U, ulcer.

TABLE 73.2

Major Noninfectious Causes of Papules, Nodules, and Ulcers

Disease Entity	Skin Lesions
Acne vulgaris	P, N
Amyloidosis	P, N
Arthropod bite hypersensitivity reaction	P, N
Autoimmune disease (SLE, dermatomyositis, Behçet)	P, N, U
Calcinosis cutis	P, N, U
Dermatofibroma	P, N
Dermoid cyst	P, N
Drug hypersensitivity reaction	P
Eczema, follicular	P
Elastosis perforans serpiginosa	P
Epidermal cyst	P, N
Eruptive vellus hair cyst	P
Erythema induratum	N, U
Erythema multiforme	P, U
Erythema nodosum leprosum	N
Factitial panniculitis	N
Foreign-body reaction	P, N

Fox–Fordyce disease	P
Gout	P, N, U
Granuloma annulare	P, N
Juvenile xanthogranuloma	P, N
Kawasaki disease	P
Keloid/hypertrophic scar	P, N
Keratosis follicularis (Darier disease)	P
Keratosis pilaris	P
Langerhans cell histiocytosis	P, N, U
Leukemia	P, N
Lichen nitidus	P
Lichen planus	P, U
Lipoma	N
Lupus erythematosus	P, U
Lupus panniculitis	N
Lymphoma	P, N
Lymphomatoid granulomatosis	N, U
Mastocytoma	P, N
Melanoma	P, N, U
Metastasis, cutaneous	P, N, U
Miliaria rubra	P
Milium	P
Necrobiosis lipoidica diabeticorum	N, U
Neuroblastoma	N
Neurofibroma	P
Neutrophilic dermatosis (Sweet syndrome)	P, N, U
Nevus	P
Panniculitis	N, U
Pilar cyst (trichilemmal cyst)	P, N
Pilomatricoma	P, N
Pityriasis rubra pilaris	P
Polyarteritis nodosa	N, U
Polymorphous light eruption	P
Prurigo nodularis	P, N
Pseudoxanthoma elasticum	P
Psoriasis	P
Pyoderma gangrenosum	N, U
Pyogenic granuloma	P
Rheumatoid nodule	N
Sarcoidosis	P, U
Spitz nevus	P, N
Steatocystoma multiplex	P, N
Subcutaneous fat necrosis	N
Superficial thrombophlebitis	N
Trichoepithelioma	P, N
Tuberous sclerosis	P
Urticaria	P
Urticaria pigmentosa	P, N
Vascular malformation	P, N
Vasculitis	P, U
Xanthoma	P, N

N, nodule; P, papule; SLE, systemic lupus erythematosus; U, ulcer.

Particular cutaneous lesions can be associated with a specific organism (e.g., umbilicated papule with molluscum contagiosum [MC], hyperkeratotic papule with human papillomavirus [HPV]), or multiple morphologic lesions can occur through the course of infection due to a single organism. For example, in tuberculosis or sporotrichosis, an initial papule can enlarge to form a nodule and then break down to an ulcer. The papular or nodular lesions can consist of a proportionately large volume of the infectious agent (e.g., poxvirus of MC), almost exclusively of inflammatory cells (e.g., histiocytes within well-controlled primary cutaneous tuberculosis), or frequently a combination of the inciting agent and inflammatory reaction.

Nodular lymphangitis, often referred to as *sporotrichoid spread* in dermatology, is a distinctive, underrecognized pattern resulting from cutaneous inoculation of a relatively limited number of agents characterized by a linear pattern of lymphadenopathy often proximal to the site of the primary inoculation (e.g., *Sporothrix schenckii, Francisella tularensis, Alternaria, Nocardia brasiliensis, Mycobacterium marinum,* other *Mycobacterium* species, *Leishmania, Yersinia* and *Francisella*).[1–6] Chronic nodular lymphangitis due to any cause can become ulcerative.[3,4]

A variety of nonspecific reactive lesions can manifest in the skin as a result of an infectious process elsewhere (e.g., erythema nodosum as a sign of streptococcal pharyngitis). The eruptions result from a disordered immune response after infection. At the time of lesion development, organisms usually are not recoverable (Box 73.1 and Table 73.3). Drug reactions in children also can manifest as papules or rarely as nodules, often in the setting of a concurrent viral infection, which can be confused with a response to the infection.

Box 73.1

Infectious Agents Associated With Erythema Nodosum

Bacteria

Bartonella henselae[a]

Brucella spp.

Campylobacter jejuni

Corynebacterium diphtheriae

Francisella tularensis

Haemophilus ducreyi

Leptospira interrogans

Neisseria gonorrhoeae

Neisseria meningitidis

Salmonella spp.

Streptococcus mutans

Streptococcus pyogenes[a]

Yersinia enterocolitica[a]

Yersinia pseudotuberculosis

Chlamydia

Chlamydophila psittaci

Chlamydia trachomatis (i.e., lymphogranuloma venereum)

Chlamydophila (Chlamydia) pneumoniae

Fungi

Blastomyces dermatitidis

Coccidioides immitis[a] dermatophytoses (e.g., tinea capitis)

Histoplasma capsulatum

Sporothrix schenckii

Helminths

Ancylostoma duodenale

Necator americanus

Mycobacteria

Mycobacterium bovis

M. leprae

M. marinum

M. tuberculosis[a]

Mycoplasma

Mycoplasma pneumoniae

Protozoa

Toxoplasma gondii

Treponemes

Treponema pallidum

Viruses

Crimean-Congo hemorrhagic fever virus

Epstein-Barr virus

Hepatitis virus B and C

Herpes simplex virus

Mumps virus

Paravaccinia virus

TABLE 73.3

Conditions With Sterile Papular, Nodular, or Ulcerative Skin Lesions After Infection

Disease Entity	Skin Lesions	Infectious Agent
Autosensitization	P, N	See Box 73.3
Erythema elevatum diutinum	P, N	*Streptococcus pyogenes*
Erythema multiforme	P	See Chapter 72
Erythema nodosum	N	See Box 73.1
Gianotti-Crosti syndrome	P	See Box 73.2
Guttate psoriasis	P	*Streptococcus pyogenes,* EBV, Chikungunya virus
Henoch-Schönlein purpura	P, N	*Brucella* sp, HBV, HEV, HIV, *Helicobacter pylori, Mycobacterium tuberculosis, Mycoplasma pneumonia, Pneumocystis jirovecii, Staphylococcus* sp, *Streptococcus pyogenes* coxsackievirus
Polyarteritis nodosa	P, N, U	Cytomegalovirus, HBV, HCV, HIV, *M. tuberculosis, S. pyogenes, Toxoplasma gondii*
Postscabitic nodule	P, N	*Sarcoptes scabiei*
Reactive arthritis		Multiple causes[a]
• Circinate balanitis	U	
• Keratoderma blennorrhagicum	P, N	
Rheumatic fever	N	*S. pyogenes*
Unilateral laterothoracic exanthema	P	Multiple viral causes[b]
Urticaria	P	See Chapter 72
Common exanthema	P	Multiple viral causes[c]

[a] Sexually transmitted form follows infection with *Chlamydia trachomatis*. The postdysenteric form follows infection with *Salmonella* and *Shigella* species, *Yersinia enterocolitica*, *Yersinia pseudotuberculosis*, *Campylobacter fetus*, and *Clostridium difficile*.

[b] Implicated agents are EBV, PIV, and adenovirus.

[c] Associated viruses include enteroviruses, EBV, human herpesviruses 6 and 7, and respiratory viruses such as RSV, PIV, and adenovirus.

EBV, Epstein-Barr virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HEV, hepatitis E virus; HIV, human immunodeficiency virus; N, nodule; P, papule; PIV, parainfluenza virus; U, ulcer.

Data from references 49–65.

This chapter focuses on diseases that can cause papules, nodules, or ulcers. Infections in which skin lesions do not develop primarily but are manifestations of systemic disease (e.g., bartonellosis, tularemia, trypanosomiasis) are discussed elsewhere.

Molluscum Contagiosum

MC is one of the most common cutaneous infections arising in childhood, and it produces a papule in the skin in which viral particles can be identified easily.[7,8] Molluscipoxvirus is as a rule found in abundance within MC lesions, whereas HPV is found in various quantities within the cutaneous lesions of common warts. Papular lesions in MC develop largely from hyperproliferation of basal cells and retention of upper epidermal keratinocytes.

Molluscipoxvirus that causes MC is a double-stranded DNA virus that replicates in the cytoplasm of host epithelial cells (see Chapter 202). Infection is acquired through direct contact with an infected person or from fomites, and it is spread by autoinoculation. School-aged children who are otherwise well and people with impaired cellular immune function are affected most commonly.[9] Children with a history of atopic dermatitis and impaired skin barrier function appear to be at greater risk for the development and spread of lesions. The pruritic nature of the underlying dermatitis makes children more likely to scratch affected areas and autoinoculate through breaks in the skin. The estimated incubation period is 2 to 8 weeks, but it can be longer.

One mechanism the virus uses to evade host mechanisms for killing virus-infected cells is its viral FLICE-like inhibitory protein (FLIP). Viral FLIPs inhibit apoptosis-mediated cell death.[10,11]

Lesions of MC are discrete, pearly pink, or skin-colored, dome-shaped papules 1 to 5 mm in the greatest dimension (Fig. 73.1), which on close inspection have central umbilication. Lesions can coalesce into larger papules or become erythematous and inflamed. In some cases, a plug of cheesy, whitish material can extrude from the center and can be mistaken for purulence. Papules can occur anywhere on the body, but there is predilection for the face, trunk, and sites where skin is in contact with other skin surfaces, such as the thighs and axillae. When the lesions are found in clusters on the genitalia or in the groin of a sexually active adolescent, other sexually transmitted infections should be sought because these lesions can result from sexual contact. Lesions commonly involve the genital area in children and frequently are not acquired by sexual transmission, but an interview and examination for other signs that may suggest sexual abuse should be performed.

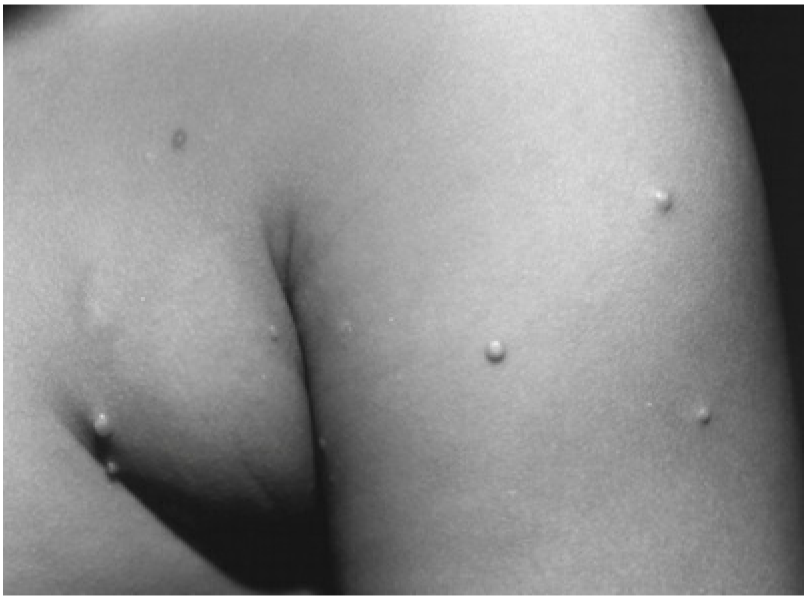

FIGURE 73.1 Umbilicated papules on the upper arm and chest of a child with molluscum contagiosum.

Mild surrounding erythema often heralds resolution of molluscum. An eczematous dermatitis can accompany the papules, especially in children with a history of atopic dermatitis or eczema.[12] Lesions in children with the acquired immunodeficiency syndrome (AIDS) tend to be large and numerous, particularly on the face, and they can have an atypical appearance, which includes coalescent crusted lesions and large, separate lesions on an erythematous base.[13] Exuberant lesions also occur in children with leukemia or other immunodeficiencies.[13]

The diagnosis of MC often is made by the typical appearance of umbilicated papules, but if lesions are clinically atypical, histologic confirmation may be warranted. On microscopic examination, the papule of MC consists of a lobulated mass of virus-infected epidermal cells. These eosinophilic viral inclusion bodies (i.e., Henderson-Patterson or molluscum bodies) become more prominent as infected keratinocytes move upward from the basal layer to the stratum corneum. The central plug of material, which is composed of virus-laden cells, can be shelled out from a lesion and examined under the microscope with 10% potassium hydroxide or with Wright or Giemsa stain. The rounded, cup-shaped mass of homogeneous cells, often with identifiable lobules, is diagnostic.

The differential diagnosis for an immunocompetent child includes noninfectious papules such as pilomatricoma, trichoepithelioma, ectopic sebaceous glands, syringoma, hidrocystoma, and an atypical melanocytic proliferation or Spitz nevus. In immunosuppressed individuals such as those with HIV infection, disseminated deep fungal infections such as cryptococcosis and histoplasmosis can be indistinguishable clinically from MC.[14,15]

MC is a self-limited, epidermal disease. The average duration is 6 to 12 months, although lesions can persist for years,[16] can spread to distant sites, can become secondarily infected with bacteria, and can be transmitted to others. Affected persons should be advised to avoid sharing baths and towels until the infection has cleared. Infection can spread rapidly and produce hundreds of lesions in children with atopic dermatitis or immunodeficiency.[9] Treatment should be considered to eliminate symptoms of pruritus or discomfort, to eliminate visible lesions, and to prevent scarring, superinfection, acquisition of additional lesions, and spread to contacts.

There are few randomized, controlled studies to assess the effectiveness of various treatment modalities in children; most reports are anecdotal. Common therapies include destructive, immunomodulatory, and antiviral measures. Spontaneous resolution or active management can result in postinflammatory pigment changes or a residual shallow atrophic scar.

Cantharidin is considered by many physicians to be very effective therapy for lesions in certain locations after its usually painless in-office application by a trained physician or other healthcare personnel.[17,18] After application, treated lesions develop a superficial blister or inflammation significant enough to result in the loss of the infectious molluscum body. Additional in-office destructive treatments include cryotherapy and curettage before which application of topical anesthetic is indicated to reduce discomfort. A brief, 6- to 9-second topical application of liquid nitrogen is effective. The molluscum body also can be expressed with a needle, a sharp curette, or a comedo extractor.

Once-daily topical application of a retinoic acid product can incite an inflammatory response, which may lead to resolution of lesions, and it is the treatment of choice for MC on the face and genital skin. Cidofovir (i.e., intravenous and topical) has been beneficial for the treatment of immunocompromised adults with severe, recalcitrant MC and in several pediatric cases.[19,20] Due to significant adverse events and toxicity, cidofovir is not indicated for healthy children with self-limited infections.[20]

The role of topical application of imiquimod in children is controversial.[21,22] A retrospective analysis of 170 children with MC demonstrated resolution of approximately 50% of molluscum lesions within 12 months with or without treatment. Although limited by methodology and sample size, the study findings challenge the trend toward treatment.[23]

Erythema Nodosum

Erythema nodosum (EN) is a form of panniculitis that typically manifests as the sudden appearance of tender, erythematous, 1- to 10-cm nodules that are usually located symmetrically on the extensor surfaces of the legs[24] (see Fig. 160.1K). Less commonly, lesions can arise at other sites, including the trunk, upper extremities, head, and neck. Rare in children younger than 2 years of age, EN is most common in adolescents. Nodules typically enlarge over a few days, remain stable for 1 to 2 weeks, and then resolve gradually over 3 to 6 weeks, with color changes that mimic a bruise. Ulceration, suppuration, and scarring do not occur, but residual hyperpigmentation can persist for weeks to months. Patients often have fever, chills, malaise, leukocytosis, and an elevated erythrocyte sedimentation rate.

EN is a hypersensitivity reaction to many triggers, but in US children, it most commonly is associated with group A streptococcal pharyngitis (see Box 73.1). Infection precedes the onset of EN by approximately 3 weeks. A variety of other infectious agents have been associated with EN, most notably tuberculosis (worldwide),[25] coccidioidomycosis (southwestern United States), *Yersinia enterocolitica* (Europe), *Bartonella henselae* (cat-scratch disease), and tularemia. EN also is associated with the use of drugs (e.g., sulfonamides, oral contraceptives), sarcoidosis, and occasionally with malignancies such as leukemia and lymphoma and systemic diseases such as Behçet disease, reactive arthritis, systemic lupus erythematosus, and inflammatory bowel disease.

The differential diagnosis includes insect bite hypersensitivity reaction, lupus panniculitis, factitial panniculitis, superficial thrombophlebitis, polyarteritis nodosa, necrobiosis lipoidica diabeticorum, erythema induratum, erythema nodosum leprosum, and sarcoidosis. Sweet syndrome (i.e., painful, indurated cutaneous plaques accompanied by fever and leukocytosis) also should be considered. Sweet syndrome can be associated with hematologic malignancies or chronic, recurrent, multifocal osteomyelitis.[26,27]

The pathogenesis of EN is poorly understood. EN is classified as a septal panniculitis without vasculitis and is regarded as an immunologic reaction to etiologic antigenic stimuli.

Diagnosis usually is made clinically, but skin biopsy can be useful to confirm the diagnosis and exclude other conditions. Histopathologic analysis reveals septal panniculitis without vasculitis, with inflammation and thickening of the fibrous septa of the subcutaneous fat. In early lesions, the inflammatory infiltrate is predominantly composed of neutrophils. Lesions in a later stage show an infiltrate composed of lymphocytes, giant cells, and granulation tissue,[28] but the changes of leukocytoclastic and lymphocytic angiitis are not seen. Foreign body–type giant cells are typical.

EN is self-limited and usually resolves within 3 to 6 weeks. Recurrent EN, such as that due to repeated streptococcal infections, can occur in children. Potential triggers should be identified and treated. Nonsteroidal anti-inflammatory agents may provide symptomatic relief. Leg elevation and bed rest can minimize lower extremity edema and decrease discomfort. Potassium iodide treatment may hasten resolution of the nodules.[29]

Gianotti-Crosti Syndrome

Gianotti-Crosti syndrome, also known as *papular acrodermatitis of childhood* (PAC), is characterized by erythematous papules that are distributed symmetrically on the extremities, buttocks, and face of children. The syndrome initially was reported in association with hepatitis B virus (HBV) infection. However, a variety of viral infections (frequently infections of the upper respiratory tract) and immunizations have been associated with the syndrome (Box 73.2).[30] Cutaneous viral infections due to poxviruses, such as molluscum contagiosum and milkers' nodules also have been associated with a Gianotti-Crosti–like reaction.[12,31] Since universal HBV immunization in the United States, Epstein-Barr virus infection has become the most common association with Gianotti-Crosti syndrome.[32]

Box 73.2

Infectious Agents Associated With Gianotti-Crosti Syndrome

Immunizations

Bacille Calmette-Guérin

Diphtheria

Tetanus

Pertussis

Measles, mumps, and rubella (MMR)

Haemophilus influenzae type b (Hib)

Hepatitis A and B

Oral poliomyelitis

Japanese B encephalitis

Influenza

Varicella

Viruses

Adenoviruses[a]

Coxsackievirus A16, B4, and B5[a]

Cytomegalovirus

Echovirus 7 and 9[a]

Epstein-Barr virus[a]

Hepatitis virus A, B,[a] and C

Herpes simplex virus type 1 (HSV-1)

Human herpesvirus 6 (HHV-6)

Human immunodeficiency virus (HIV)

Parainfluenza viruses[a]

Parvovirus B19

Poliovirus

Respiratory syncytial virus[a]

Rotavirus

---

[a] Most common.

Data from references 30, 45, and 46.

The disorder classically has a sudden eruption of symmetric, flat-topped, discrete, erythematous, 2- to 10-mm papules on the face, upper and lower extremities, and buttocks. The trunk and antecubital and popliteal fossae usually are spared or less involved. Patients can have pruritus and the Koebner phenomenon (i.e., accentuation of lesions at sites of trauma). Peak incidence is between 1 and 4 years of age. The differential diagnosis includes drug eruption, papular forms of urticaria, erythema multiforme, viral eruption, pityriasis lichenoides, and Langerhans cell histiocytosis.

The pathogenesis of the syndrome has been suggested to be an immunoreactive process, perhaps mediated by immune complexes or due to delayed hypersensitivity.[33] When associated with HBV infection, lesions have not yielded evidence of immune complex vasculitis, and the HBV surface antigen has not been demonstrated in skin lesions.

The syndrome usually is self-limited, resolving within 3 to 6 weeks. Lesions occasionally can persist for a few months, and relapses, although rare, have been reported. Treatment is supportive and does not shorten the course of the skin lesions. Orally administered antihistamines may provide symptomatic relief. The response to topical corticosteroids is debatable.

Other Exanthematous Infections

Numerous infections can manifest as papular, or less commonly, ulcerative eruptions on the skin. The bilaterally symmetric exanthem or morbilliform eruption classically progresses cephalocaudad and often is caused by a variety of viruses[34] (see Chapter 69). A careful history and review of systems often can elicit the necessary signs and symptoms to determine the underlying infectious cause.

Morphologically unique eruptions such as unilateral laterothoracic exanthem (i.e., asymmetric periflexural exanthem) deserve recognition to identify possible underlying infectious causes. Exanthems can have an atypical appearance such as ulcerative lesions (e.g., bacterial superinfection of primary vesicular herpes simplex virus [HSV] or varicella-zoster virus [VZV] lesions). Certain strains of bacteria (e.g., group A streptococci) can be associated with exanthems, such as the papular eruption of scarlet fever.

Autosensitization Reaction

A symmetric papular or papulovesicular cutaneous eruption can arise at a site distant to the primary dermatitis and is known as *autosensitization* or an *id reaction*. Id reaction likely is caused by hematogenously circulating products or the resultant host immune response, or both. Most commonly triggered by noninfectious causes such as a contact dermatitis, the id reaction frequently follows dermatophyte or bacterial infections (Box 73.3).[34,35]

Box 73.3

Infectious Agents Associated With a Papular or Nodular Autosensitization (Id) Reaction

[a] Most common.

Data from references 47 and 48.

Epidermal cytokines released from sites of skin infection can cause the heightened sensitivity of skin at sites distant from the site of infection to a variety of stimuli that usually are innocuous. Culture and potassium hydroxide examination of id lesions do not reveal the organism, but the test result for *Trichophyton* skin reactivity is positive. The most common dermatophyte infection triggering a dermatophytid reaction is tinea pedis, although id lesions also can occur in the setting of tinea capitis and tinea corporis. Although less commonly reported, the id reaction to tinea capitis manifesting as an eczematous eruption has been seen in children before or after initiation of systemic antifungal therapy. Antifungal therapy should be continued, and patients can be treated symptomatically with mild topical corticosteroids and oral antihistamines.[36]

Tuberculid reactions are another example of autosensitization.[25] Their genesis appears to be different from that of dermatophytid reactions. Skin lesions are rare, usually appearing in a host who has moderate to strong tuberculin reactivity, has a history of tuberculous infection of other organs, and usually has shown a therapeutic response to antituberculous therapy. Lesions exhibit tuberculoid features histologically but do not contain detectable mycobacteria, although organisms may be detected with methods such as polymerase chain reaction. Tuberculid reactions represent the paucibacillary pole of disease.[25] Rapid local destruction may account for the absence of bacilli in lesions.

The most commonly observed tuberculid in children is lichen scrofulosorum, which is characterized by asymptomatic, grouped, pinhead-sized, often follicular, pink or red papules that form plaques, mainly on the trunk.[37] Healing occurs without scarring. On histopathologic examination, granulomas are seen in the superficial dermis, often surrounding follicles and the ducts of sweat glands. The inflammatory infiltrate contains epithelioid cells, giant cells, and a rim of lymphocytes. Caseation usually is absent. These lesions can be difficult to distinguish clinically and histopathologically from lichenoid sarcoidosis.

Erythema induratum, another form of tuberculid, is a panniculitis associated with tuberculosis infection. Unlike EN, erythema induratum has a tendency to affect the posterior aspect of the lower extremities, although both have a predilection for female patients. Both erythema induratum and the papulonecrotic tuberculid form (i.e., vesicular eczema) often are associated with pulmonary tuberculosis.

In papulonecrotic tuberculid cases, recurrent crops of symmetrically distributed, asymptomatic, firm, sterile, dusky red papules appear on the extensor aspects of the limbs, the dorsum of the hands and feet, and the buttocks. They also may represent the paucibacillary form of intravascular dissemination. Papules can undergo central ulceration and eventually heal, leaving sharply delineated, circular, depressed scars. Lesions are characterized histopathologically by a wedge-shaped area of upper dermal necrosis, with the broad base toward the epidermis, surrounded by a tuberculoid inflammatory infiltrate. Obliterative vasculitis is found in the deep dermis. The duration of the eruption varies, but lesions usually disappear promptly after treatment of the primary infection. Similar tuberculid-like reactions have been seen after bacille Calmette-Guérin (BCG) vaccination.[38]

In addition to dermatophytids and tuberculids, autosensitization has been reported with bacterial (e.g., pharyngitis), spirochetal (e.g., syphilis), and viral (e.g., molluscum contagiosum) infections.[39] These reactions also can occur in response to noninfectious stimuli. A common pediatric example is an id reaction occurring with severe contact dermatitis to nickel. In this example, an eczematous dermatitis can occur at sites distant from the affected area of contact dermatitis.

Subcutaneous Tissue Infections and Abscesses

Catalina Matiz, Sheila Fallon Friedlander

Infection of soft tissues can involve the skin, subcutaneous tissues, fascia, and skeletal muscle or a combination of these structures. The *subcutaneous compartment* is continuous over the entire body and consists of fat and loose connective tissue containing blood and lymphatic vessels underlying the dermis.[1] The *fascia* is subdivided into superficial and deep components. The *superficial fascia,* between the dermis and the deep fascia, is further subdivided into two layers. The outer layer, which is closest to the dermis, has various thicknesses and contains loose collagenous tissue and fat. The inner layer of the superficial fascia is a thin membrane that has relatively little fat but is rich in elastic tissue. Superficial arteries, veins, nerves, and lymphatics lie within the superficial fascia. The *deep fascia* is a membranous sheet surrounding muscles and separating them into functioning units, and it forms the deepest boundary of the subcutaneous tissue compartment.

Infections of the skin and subcutaneous tissues can be classified by site of involvement (Box 74.1) and as primary, secondary, or tertiary, depending on the mechanism of infection. *Primary infections* originate directly in skin that grossly appears to be clinically normal, although minor breaks in the integrity of the barrier function may be required (see Chapter 68). Some infections, such as folliculitis, furunculosis, carbunculosis, and paronychia, evolve into abscesses and occasionally extend from the epidermis or dermis to involve deeper subcutaneous tissues

Tropical ulcer

Synergistic necrotizing cellulitis

Myositis (see Chapter 75)

Pyomyositis (see Chapter 75)

Secondary infections, which occur in previously diseased or wounded skin, include infection of cysts (e.g., epidermal inclusion, pilar cyst), ulcers (e.g., decubitus ulcer), wounds (e.g., surgical or traumatic wound; burns; scalp electrode sites; arthropod, animal, or human bites, burrows due to scabies, flies, or fleas), and those occurring in areas of dermatitis (e.g., atopic dermatitis, psoriasis). These infections also can spread contiguously to deeper subcutaneous tissue.

Tertiary infections develop when pathogens are spread hematogenously or through lymphatics to soft tissues from a distant focus (e.g., *Clostridium septicum* necrotizing fasciitis or myonecrosis, *Staphylococcus aureus* abscess). These infections can involve any of the deeper soft tissues, but they usually spare direct involvement of the epidermis. Compromise of blood flow of nutrient vessels or extension of an infectious and inflammatory nidus to the epidermis and dermis can result in cutaneous disease.

Many conditions predispose patients to subcutaneous tissue infections and abscesses (Box 74.2). The infections also can be classified as nonpurulent (i.e., erysipelas, cellulitis, and necrotizing fasciitis) or purulent (i.e., furuncles, carbuncles, and abscesses).[2]

[a] Associated with abscess formation.

Etiology

The cause of abscesses and subcutaneous infections in children is not always clear. A study of 246 patients between 4 days and 17 years of age who were seen in an emergency department for skin and soft tissue infections found an increase in the proportion of abscesses from 14% (in 2003) to 65% (in 2008) that most commonly occurred in the buttock area. The most commonly identified abscess pathogen in this study was community-associated, methicillin-resistant *S. aureus* (CA-MRSA).[3]

Identification of the pathogens causing a particular subcutaneous soft tissue infection or, in some cases, exclusion of a variety of noninfectious conditions in the differential diagnosis of subcutaneous tissue infections (Box 74.3) requires proper use of diagnostic tests and interpretation of results. If the surface of a wound or site of infection is sampled with a swab, several organisms can be isolated that are colonizing the area but may not be contributing to the disease process. If an organism is suggested by Gram stain (or special stains in the case of fungi) and identified by culture, the likelihood of its pathogenicity is increased. Chances of identifying the true pathogen are improved further if culture specimens are obtained by decontaminating the skin and then using a no. 11 blade to express material, by swabbing the exudate from a site of suppuration or using fine-needle aspiration, or by performing a punch or excisional biopsy.[4]

Purpura fulminans

Pyoderma gangrenosum

Sweet syndrome (i.e., acute febrile neutrophilic dermatosis)

Cultures should be obtained for routine and fastidious, aerobic and anaerobic organisms when appropriate. Sampling to identify fungi and viruses, including herpes simplex virus (HSV) and cytomegalovirus (CMV), particularly in immunocompromised patients, usually is appropriate. Susceptibility testing should be performed to guide antibiotic therapy except for anaerobes and *S. pyogenes*, unless therapy other than with a β-lactam agent is contemplated. Remember that sulfonamides are not appropriate for treatment of streptococcal infections.

This chapter describes infections that lead to abscess formation and tissue necrosis involving subcutaneous tissues as deep as the inner layer of the superficial fascia. Infections that commonly extend into the deep fascia and muscle are discussed elsewhere (see Chapter 75).

Abscesses

An abscess is a localized, usually inflamed, walled-off collection of purulent exudate formed by a collection of white blood cells (WBCs), bacteria, and disintegration or necrosis of tissue. An abscess is recognized clinically as a firm, tender, erythematous nodule that is fluctuant. The initial skin lesion commonly can be mistaken for a spider bite.

A subcutaneous abscess most commonly evolves by local extension of a primary infectious process in the epidermis or dermis, such as a cutaneous abscess originating from a skin appendage such as a pilosebaceous unit (e.g., furuncle, carbuncle, infundibular cyst, periporitis) or secondarily from a site of skin disease or injury. A subcutaneous abscess also can arise by direct traumatic implantation or invasion of pathogens into subcutaneous tissue or occasionally by hematogenous spread.

In the patient with an abscess, constitutional symptoms usually are initially absent, unless the process has extended into deeper tissues or the bloodstream. Often, no predisposing factor can be identified, although several processes that disrupt the integrity of the barrier function of the skin or the integrity of local immunologic processes, particularly neutrophil function, are associated with abscess formation. Patients with hyperimmunogobulin E syndrome and chronic granulomatous disease are subject to abscess formation. Despite the extensive list of immunodeficiency diseases associated with abscess formation, most people with recurrent abscesses lack evidence of immunodeficiency.

Pathogenesis

The principal pathogens of subcutaneous abscesses in children are shown in Box 74.4, and they vary with body site. The single most common pathogen is *S. aureus*.[5] CA-MRSA is responsible for more than 60% of the cases of abscesses in children in certain centers in the United States.[6,7]

CA, community-associated; MRSA, methicillin-resistant *Staphylococcus aureus;* MSSA, methicillin-susceptible *Staphylococcus* *aureus.*

CA-MRSA possesses the staphylococcal cassette chromosome mec (SCCmec) (types IV–V), which contains the *mecA* gene complex responsible for antibiotic resistance. The USA300 clone most commonly causes skin and soft tissue infections in the United States.[8] CA-MRSA abscess formation is thought to be associated with Panton-Valentine leukocidin, which causes leukocyte destruction and tissue necrosis, and with α-type phenol-soluble modulins (PSMs). The type I arginine catabolic mobile element (ACME) promotes growth and survival of clone USA300 in the cutaneous surface and enables the bacteria to colonize human skin.[9,10]

Table 74.1 shows groups at risk for CA-MRSA skin and soft tissue infections. As the epidemic of CA-MRSA spread, however, it became clear that many affected children had no risk factors.

TABLE 74.1

Antibiotic Therapy for Cutaneous Abscesses in an Era of Community-Associated, Methicillin-Resistant *Staphylococcus aureus* Infections

Treatment Groups	Antibiotic	Clinical Remarks
Empiric therapy	Clindamycin	If geographic *S. aureus* resistance rate ≤10%
	Trimethoprim-sulfamethoxazole (TMP-SMX)	TMP-SMX alone is inadequate for group A *Streptococcus*. TMP-SMX could be used in combination with a β-lactam agent
	Doxycycline	For children ≥8 years of age
	Minocycline	For children ≥8 years of age
	Linezolid	
Hospitalized patients	Vancomycin	Gold standard for hospitalized patients
	Linezolid, IV or PO	
	Daptomycin	For patients intolerant of vancomycin (not approved for use in children)
	Clindamycin, IV or PO	Depending on low rate of resistance (≤10%)

Occasionally, anaerobic bacteria appear to act alone to cause abscesses. Encapsulated anaerobic bacteria usually are most important.[11] This finding contrasts markedly with observations of pediatric superficial skin infections, in which anaerobic bacteria rarely play a pathogenic role.[12] Anaerobic bacteria also do not act alone to cause necrotizing soft tissue infections in immunocompetent people.[13] Cultures from perineal or perioral abscesses and ulcers in children and adults usually contain organisms that reside normally on adjacent mucous membranes rather than skin, whereas lesions remote from the rectum or mouth primarily contain organisms that reside normally on skin at that site.[5,14–20]

Overall, the most common aerobic and facultative bacteria isolated from cutaneous and subcutaneous abscesses and decubitus ulcers in children are CA-MRSA followed by community-associated, methicillin-susceptible *S. aureus* (CA-MSSA) and less often by *Proteus Mirabilis* and *S. pyogenes*.[7,15] Streptococci (i.e., α-hemolytic and nonhemolytic), *Enterococcus* spp., enteric gram-negative bacilli, *Pseudomonas aeruginosa,* and anaerobes are associated especially with decubitus ulcers.[5,20] Immunocompromised hosts are at risk for abscess formation due to a broader spectrum of pathogenic microbes, including fungi (see Box 74.4).[21]

Management

Incision and drainage of abscesses in a healthy host may be the only therapeutic approach necessary.[15,22,23] The addition of systemic antibiotic therapy is recommended if the patient has signs and symptoms of illness, rapid progression, failure to respond to incision and drainage alone, associated comorbidities or immunosuppression, abscess in an area difficult to drain (e.g., face, hand, genitalia), or associated phlebitis.[15,23] Because of the prevalence of CA-MRSA, clindamycin or trimethoprim-sulfamethoxazole (TMP-SMX) are acceptable first-line treatment options for uncomplicated abscesses in geographic areas where CA-MRSA usually is susceptible to clindamycin.[24] TMP-SMX should not be considered if associated streptococcal infection is suspected.

Guidelines for treatment of CA-MRSA skin and soft tissue infections from the Infectious Diseases Society of America (IDSA) are shown in Table 74.1.[23] A US multicenter prospective, randomized superiority trial enrolling 524 patients (155 children) with uncomplicated cellulitis or an abscess larger than 5 cm demonstrated no difference in efficacy between clindamycin and TMP-SMX (all abscesses were drained).[24] More aggressive therapy for skin abscesses is recommended for immunocompromised patients, patients with recurrent furunculosis, very young patients, or patients who appear ill. Intravenous therapy is reserved for those with moderate to severe, localized or systemic disease and those unable to tolerate oral medications.

Considerations by Clinical Site

Breast Abscess

Breast abscess is an uncommon infection of neonates that is usually caused by *S. aureus* and occasionally caused by group A or B *Streptococcus, Escherichia coli, Klebsiella, Salmonella* spp., *Proteus mirabilis,* or *P. aeruginosa.* Although anaerobic organisms can be isolated from up to 40% of infections, their exclusive pathogenic role in neonates is questionable, and therapy directed specifically against anaerobes usually is unnecessary.[25,26] Breast abscess develops in term neonates during the first 6 weeks of life, most commonly during the second to fourth week.[25–30]

Incidence of breast abscess is twofold higher in girls overall, but it is approximately equal in boys and girls during the first 2 weeks of life.[27] Physiologic breast enlargement, which is more common in infant girls than in boys older than (but not younger than) 2 weeks of age,[31] probably is a factor in the pathogenesis, as also evidenced by the absence of breast enlargement and breast abscess in premature infants.[27] Other factors are involved, and a relatively large, retrospective review of neonates with breast abscess found that only about one half had breast enlargement before development of an abscess.[27] It is likely that organisms from the nasopharynx or umbilicus colonize the skin of the nipple and move retrograde through the glandular ducts of physiologically enlarged breasts.[32]

Breast enlargement accompanied by various degrees of erythema, induration, and tenderness occurs initially and can progress to fluctuation, depending in part on how promptly antibiotic therapy is initiated. Bilateral infection is rare. Fever or constitutional symptoms such as irritability and toxicity affect approximately one third of cases, although leukocytosis (WBC >15,000 cells/mm^3) is found in approximately one half to two thirds of patients.[25] Breast abscess due to *S. aureus* is accompanied by cutaneous pustules or bullae on the trunk, particularly in the periumbilical or perineal region, in 25% to 50% of patients.[27] The symptoms, age at presentation, and clinical findings for infections due to gram-negative bacilli or anaerobes are similar to those for staphylococcal abscesses, except that infants infected with *Salmonella* spp. also can have gastrointestinal symptoms.[29]

The most common complication of breast abscess is cellulitis, which develops in approximately 5% to 10% of affected infants.[27] Cellulitis usually is localized but rarely can extend rapidly over the shoulder or abdomen.[28] Other complications, such as bloodstream infection (BSI), pneumonia, and osteomyelitis, are unusual. Scar formation leading to decreased breast size after puberty can be a late sequela.[27]

Results of Gram stain and culture of material expressed from the nipple or obtained by needle aspiration or incision and drainage help guide antibiotic therapy. If the lesion is fluctuant, the abscess must be drained; antibiotic therapy is adjunctive. If fluctuation is absent, antibiotic therapy alone may be curative. Warm compresses also may be beneficial. In areas with a high incidence of MRSA infections, systemic vancomycin or clindamycin is given; otherwise, nafcillin (or cefazolin if there is no concern about BSI or meningitis) is an option for MSSA. If gram-negative bacilli or no organisms are seen on Gram stain or the infant appears ill, initial therapy also should include an aminoglycoside agent or other antibiotic with gram-negative bacillary coverage. In most instances, a 5- to 7-day course of therapy is sufficient, although the total course of therapy sometimes is 10 to 14 days. The duration of parenteral therapy depends on the isolate, occurrence of BSI, and the clinical course.

Sweat Gland Abscess

Sweat gland abscesses (i.e., periporitis) develop rarely in neonates, most often in association with malnutrition or debilitation.[33] The infection also has been called *periporitis staphylogenes* because of the almost uniform presence of *S. aureus* in the lesions. It appears that lesions of miliaria become infected secondarily, followed by extension of the infection into the sweat gland apparatus and occasionally into the adjacent subcutaneous tissue. Miliaria-like lesions, however, are not a constant feature. The 1- to 2-cm, round to oval nodular abscesses occur most commonly on the neck, occiput, back, and buttocks, and unlike furuncles and carbuncles of follicular origin, they are nontender, nonpointing, and cold. Constitutional symptoms can accompany numerous large abscesses, and lymphangitis or cellulitis occurs rarely.

Therapy consists of controlling factors such as skin occlusion or fever that predispose to miliaria, correction of malnutrition, local care of abscesses, and use of antistaphylococcal antibiotics. Healing occurs over several weeks, usually without scarring.

Axillary abscesses occur predominantly in adolescents, accounting for 6.7% of 564 culture-positive abscesses in patients evaluated in one urban emergency department.[34] In this report, 76% were female. Although 46% of axillary abscesses were caused by CA-MRSA and 24% by MSSA, a surprising 22% were caused by *Proteus mirabilis*.[34] Patients with multiple, recurrent, bilateral axillary abscesses should be evaluated for possible hidradenitis suppurativa, especially when lesions also develop in the groin, scalp, or buttocks.

Perineal Abscess

Most abscesses of the perineal (e.g., inguinal, buttock, perirectal, vulvovaginal) region contain multiple species of facultative and anaerobic fecal organisms, particularly *Bacteroides* spp. Recently, CA-MRSA has become a prevalent cause of superficial genitourinary abscesses in children.

Perineal abscesses usually require surgical debridement. Cure rates are high, and the morbidity rate is low.[35] Antibiotic therapy is adjunctive.

Perirectal Abscess

Perirectal abscesses most commonly affect children younger than 2 years of age, with an incidence that can reach 4%, and a notable predilection for boys. The abscesses are thought to occur because of a congenital anomaly of the anal crypts and an imbalance of the androgen to estrogen ratio or an androgen excess. Others have postulated that perirectal abscesses are caused by local infection of a crypt after trauma to the area.[36]

There may be no apparent predisposing factor, or the abscess can develop after minor abrasions or fissures, particularly in association with diarrhea or constipation. Older children who experience perirectal abscess more frequently have a predisposing condition such as Crohn disease, neutropenia (in association with cancer, autoimmunity, or chemotherapy), neutrophil dysfunction due to immunodeficiency, acquired immunodeficiency syndrome (AIDS), diabetes mellitus, corticosteroid therapy, ulcerative colitis, hidradenitis suppurativa, or prior rectal surgery. In those with neutropenia, the risk of perirectal abscess or cellulitis increases with perirectal mucositis, hemorrhoids, rectal fissure, or manipulation. A break in the mucosal barrier or occlusion of anal crypts usually initiates infection.

The predominant organisms in perirectal abscesses are mixed anaerobic and aerobic flora of the intestine and skin of the anal verge. The most common agent identified is *E. coli* alone or in combination with streptococci, enterococci, or anaerobes, followed by *S. aureus*. Other implicated organisms include *S. pyogenes, P. aeruginosa, Klebsiella* spp., and *Proteus* spp. Anaerobic bacteria include *Bacteroides, Peptococcus, Peptostreptococcus, Porphyromonas, Fusobacterium,* and *Clostridium* species.[37–41] Perirectal abscess rarely can be caused by *Entamoeba histolytica, Mycobacterium* spp., *Nocardia* spp., and *Actinomyces* spp. Buttock abscesses most commonly result from *S. aureus* infection, even in neonates.[37]

Superficial buttock abscess in the infant usually manifests as pain on defecation, sitting, or walking and as redness, swelling, and tenderness in the perianal region. A superficial abscess in the epithelium can extend in any of the following directions: inferiorly along the anal sphincter to exit next to the anus on the buttock (i.e., fistula-in-ano), laterally through the external sphincter to the ischiorectal fossa to form a deep abscess or superiorly to the deep space between the internal sphincter and the levator ani muscles.[42–44] An abscess in deeper tissues can be accompanied by poorly localized, deep pain and constitutional symptoms. An anorectal abscess may not be apparent externally, but pain usually is elicited on rectal examination.

In immunocompetent infants, a superficial perianal abscess can drain spontaneously (and can be self-limited) or may need to be drained surgically. Exploration of the abscess for a fistula depends on the clinical circumstances and isolation of organisms other than *S. aureus.* Empiric therapy with antibiotics to cover anaerobic and aerobic gram-negative bacilli and *S. aureus* may prevent regional spread of the infection and decrease the incidence of complications.[38] A 7- to 10-day course of therapy is recommended.

Children with granulocytopenia may have delayed development of erythema, induration, and fluctuation. In the absence of fluctuation, extensive soft tissue disease, or BSI, a trial of parenteral antimicrobial therapy alone may be initiated. Perirectal abscess in young children is less likely associated with underlying anatomic anomalies and more amenable to complete resolution with conservative nonoperative therapies. However, if progression of disease or fluctuation becomes apparent, surgery should be undertaken.

Complications, which occur more commonly in children with underlying disease, include anorectal fistula, recurrence of abscess, BSI, and necrotizing fasciitis. There is some evidence that conservative treatment with systemic antibiotics rather than drainage may be associated with a decreased risk of fistula formation in infants younger than 12 months of age.[45] A chronic fistula may require a fistulotomy.[43]

Scalp Abscess

Scalp abscess appears as a localized, erythematous area of induration that is 0.5 to 2 cm in diameter, usually at the insertion site of a fetal scalp-monitoring electrode. The site can become fluctuant, pustular, or suppurative. The abscess manifests most commonly on the third or fourth day of life (range, 1 day to 3 weeks).[46] Regional lymphadenopathy can occur, but other, more serious complications, such as cranial osteomyelitis, subgaleal abscess, and necrotizing fasciitis of the scalp, are uncommon. Death associated with a complication of fetal scalp electrode placement has been described in a premature infant who had *E. coli* scalp abscess and BSI.[47]

The incidence of scalp abscess after placement of a spiral fetal scalp electrode (i.e., the type used since the early 1970s) ranged from 0.1% to 1.0% in retrospective studies of approximately 18,000 neonates.[46] Prospective studies have reported incidences between 0.6%[48] and 4.5%.[49]

Reports of predisposing factors are conflicting. Okada and associates[49] found a significant association with longer duration of placental membrane rupture and of monitoring; monitoring for high-risk indications, particularly prematurity; and nulliparous birth, possibly because of a higher risk of infection of an edematous, hypoxic caput succedaneum. Scalp trauma and compression, however, are questionable factors in the pathogenesis of scalp abscess because most reports have not found abscess formation at sites of scalp trauma and abrasion due to forceps or vacuum extraction, at sites of fetal blood sampling, or in association with hematomas.[46,50] There are exceptions because cephalohematomas can become infected,[51] and similar rates of scalp abscess have been reported among infants who were monitored with scalp electrodes and those who were not monitored but were delivered by forceps or vacuum extraction.[52] A threefold greater but not statistically significant rate of scalp abscess has been found for infants delivered by vacuum extraction compared with those born by spontaneous vaginal delivery.[49] In one study[53] but not another,[48] an association with prolonged rupture of membranes and development of scalp abscess was found. Risk factors in the latter study included number of vaginal examinations, concurrent monitoring with an intrauterine pressure catheter, use of more than one spiral electrode, fetal scalp blood sampling, maternal diabetes, and endomyometritis.[48]

Scalp abscess typically is a polymicrobial infection. Cultures from abscesses reveal aerobic or facultative organisms alone in approximately one third, anaerobic isolates alone in 10% to 25%, and mixed aerobic or facultative and anaerobic bacteria in 40% to 60% of cases.[46,49,54] The most common aerobic isolates are *S. aureus;* groups A, B, or D streptococci; *S. epidermidis;* and occasionally *Haemophilus influenzae, E. coli, K. pneumoniae, Enterobacter* spp., *P. aeruginosa,* and *Neisseria gonorrhoeae.* The role of *S. epidermidis* as a pathogen is questionable. Common anaerobic isolates are *Peptococcus, Peptostreptococcus,* and *Bacteroides* species, *Propionibacterium acnes,* and *Clostridium* spp. The anaerobic flora in the abscesses reflects that found in cervical flora during labor. Neonatal necrotizing fasciitis of the scalp has been associated with intrapartum fetal scalp electrode monitoring.[55]

The primary differential diagnostic concern for fetal scalp abscess is HSV infection.[46] The time of appearance of herpetic lesions (peak incidence, 4 to 10 days) overlaps with that for scalp abscess, and the lesions occasionally can be indistinguishable clinically. Mucocutaneous HSV can be associated with central nervous system or disseminated disease, or both.[56] If suspicion of HSV exists, complete evaluation is indicated, and therapy with acyclovir should be initiated while awaiting results of diagnostic tests.

Infants who are subjected to scalp electrode monitoring during birth should be followed closely during the first weeks of life for evidence of infection. Parents should be instructed in surveillance. If weeping, vesiculopustular lesions or an abscess is detected, specimens should be obtained by needle aspiration or swabbing of the exudates from the puncture site for direct testing and culture of aerobic and anaerobic organisms and HSV. Many bacterial infections of the fetal scalp resolve spontaneously, but if fluctuance develops without spontaneous suppuration, incision and drainage may be necessary. Extensive debridement, however, should not be performed. For surrounding cellulitis, a 5- to 7-day course of parenteral antibiotic therapy usually is sufficient, with culture results guiding the antibiotic choice. HSV scalp lesions also can heal spontaneously, but because reactivation and dissemination can occur with serious consequences, full evaluation and polymerase chain reaction (PCR) testing of blood and cerebrospinal fluid are performed. Parenteral acyclovir therapy always should be administered for neonatal HSV scalp infection.

Necrotizing Soft Tissue Infections

Necrotizing soft tissue infections (NSTIs) are uncommon in children but are potentially life-threatening conditions characterized by rapidly advancing local tissue destruction and systemic toxicity. Tissue necrosis distinguishes them from cellulitis (see Chapter 68), in which an inflammatory infectious process involves but does not destroy subcutaneous tissues. Unlike an abscess, NSTIs involve diffuse tissue necrosis and lack localized purulence, although a subcutaneous abscess occasionally forms. These infections can occur anywhere on the body, and the most common locations are the extremities, abdomen, and perineal region. Risk factors for NSTIs in pediatric patients include trauma, surgery, chronic illness, and recent varicella infection[57]

Since the mid-1980s, there has been a resurgence of fulminant necrotizing soft tissue infections due to *S. pyogenes* and recently due to Panton-Valentine leukocidin-positive *S. aureus,* often in healthy people with little or no apparent immunologic deficiency or compromise of skin integrity (e.g., varicella-zoster virus infection). Bacterial virulence factors and absence of specific host resistance factors appear to be important in the pathogenesis.[58]

Classification of NSTIs has undergone several revisions over the years, often using more than one name for the same condition (e.g., clostridial and nonclostridial anaerobic cellulitis, bacterial synergistic gangrene, Meleney ulcer; necrotizing fasciitis, myonecrosis, gangrene) and resulting in a confusing body of literature. Most recent reviews advocate use of the term *necrotizing soft tissue infection* to include all forms of the disease process, regardless of the level of the soft tissue affected, because the approach to diagnosis and management is the same.[59]

Relatively few organisms possess sufficient virulence to cause NSTIs when acting alone (Box 74.5). Fulminating infections are caused by *S. pyogenes,* although a clinically indistinguishable NSTI can be caused by *S. aureus* (including MRSA), *Clostridium perfringens, C. septicum, P. aeruginosa, Vibrio* spp. (particularly *Vibrio vulnificus*), and fungi of the order Mucorales, particularly *Rhizopus, Mucor,* and *Absidia* spp.[58,60–63]

Streptococcus aureus

Streptococci (e.g., hemolytic, nonhemolytic nongroup A)

Although NSTIs can be monomicrobial, they more often are polymicrobial. In most cases, a mixture of anaerobic, aerobic, and facultative anaerobic bacteria appears to act together to cause tissue necrosis.[14] Anaerobic isolates are similar to those found in subcutaneous abscesses, consisting of *Bacteroides, Peptostreptococcus, Peptococcus, Prevotella, Porphyromonas, Clostridium,* and *Fusobacterium* species.[14,64] The most common aerobic or facultative bacteria are several species of hemolytic or nonhemolytic nongroup A streptococci, MRSA, *E. coli, Enterobacter* spp., and a variety of other Enterobacteriaceae and *Pseudomonas* spp.[65,66] In corticosteroid-treated patients, *Entamoeba histolytica* and nontuberculous mycobacteria (particularly *Mycobacterium kansasii* and *M. chelonae*) can cause an identical clinical syndrome.[65,67] No particular combination of organisms, however, is diagnostic for any given clinical entity that involves an NSTI. Identification of gas in infected tissue is thought to be a hallmark of clostridial infection, but most soft tissue infections with gas production are caused by facultative gram-negative bacilli, such as *E. coli, Klebsiella* spp., *Proteus* spp., and *Aeromonas* spp.[68]

Tertiary or hematogenous infections of the subcutaneous tissues occur most commonly in immunocompromised hosts and can lead to abscess or NSTI. Although a wide range of organisms, including bacteria and fungi, can be involved, the most common are *S. aureus* and *P. aeruginosa.*

Pathogenesis

Some of the same organisms that cause cellulitis can cause NSTI, with involvement of fascia or tissue necrosis. Responsible factors are poorly understood but involve a complex interaction among predisposing tissue factors such as local trauma, anaerobic wound environment, systemic and local host defense, bacterial virulence factors, and synergy of microorganisms.

Compromise of immune defense is a primary predisposing factor for development of subcutaneous infections. This process can occur locally, result from trauma or surgery that compromises the barrier function of the skin, or involve systemic immunodeficiency, especially in individuals with defective neutrophil function. Systemic immunodeficiency is especially important for the development of necrotizing infections due to *P. aeruginosa* or fungi. Innate cutaneous defenses, including the physical barrier afforded by the lipids and the cross-linked cornified envelope in the stratum corneum, appear to be sufficient most often to prevent infection. Through trauma to skin or mucosal surfaces, however, a pathogen may be able to adhere to a previously unexposed receptor or a receptor that is newly synthesized in the injured skin.

In some infections, such as those due to *Clostridium* spp., the depth of the initial injury is the most important determinant of depth of infection.[34,68] Other infections, such as necrotizing fasciitis due to *S. pyogenes,* can spread rapidly from superficial layers of the skin to deeper subcutaneous tissues, aided by poorly understood virulence factors. In infections that follow varicella, access to tissue beneath the stratum corneum at sites of chickenpox lesions may allow initiation of local infection.[69–73]

In diabetes, compromised blood flow to the skin due to small-vessel vasculopathy and impaired function of neutrophils may predispose to necrotizing infection. The relatively high incidence of subcutaneous infections in those with peripheral vascular disease due to other causes, such arthrosclerosis, supports this concept of pathogenesis, as does the fact that thrombosis of vessels is a major histologic feature of many necrotizing infections in adults.[74,75] A higher degree of vascular thrombosis has been correlated with more acute presentations of necrotizing fasciitis.[74] The cause of vascular thrombosis is not understood completely, but it probably involves direct cytolytic or thrombogenic factors released from bacterial pathogens, immune-mediated vascular damage due to the inflammatory infiltrate surrounding the blood vessels, or noninflammatory intravascular coagulation.[75] Disease in the dermis and epidermis occurs secondarily after thrombosis of deeper vessels.

Synergy of microorganisms does not appear to be necessary for abscess formation, but it does appear to be operative in many NSTIs because anaerobic or facultative organisms rarely are found alone in these infections.[14] The concept of bacterial synergy in the pathogenesis of soft tissue infection as advanced in the 1920s by Brewer and Meleney[76] involved microaerophilic (likely anaerobic) streptococci and *S. aureus*, which caused a progressive, chronic subcutaneous tissue infection called *bacterial synergistic gangrene*. Since then, numerous combinations of organisms have been found to act synergistically in subcutaneous infections.[77]

Synergistic pathogenesis of anaerobic, aerobic, and facultative bacteria is supported by clinical data and animal models, including studies of tropical ulcer showing synergistic associations of *Fusobacterium* spp., other anaerobic bacteria, and spirochetes.[78,79] In an animal model of necrotizing fasciitis, *S. aureus* or crude staphylococcal α-lysin potentiated the pathogenesis of *S. pyogenes.*[80] The mechanism of synergy appears to vary according to the organisms present, but it may result from mutual protection from phagocytosis and intracellular killing, promotion of bacterial capsule formation, production of essential growth factors or energy sources, and use of oxygen by facultative bacteria, lowering the tissue oxidation-reduction potential to facilitate growth of anaerobic organisms.[77,81,82]

Extracellular bacterial toxins and enzymes are important factors in the destruction of subcutaneous tissue.[83] In NSTI due to *Clostridium* spp. or *S. pyogenes* in children, few acute inflammatory cells can be identified in necrotic fascia and subcutaneous tissue. Necrotizing tissue infections appear to be related to the production of a variety of potent toxins and enzymes.[84]

Initiation of an NSTI appears to require a break in the skin or mucous membrane, although the injury often is blunt, trivial, or inapparent.[58] Adherence of *S. pyogenes* to respiratory tract epithelium has been postulated to involve a two-step mechanism: a relatively weak, nonspecific hydrophobic binding followed by high-affinity, specific attachment.[85] The mechanism of adherence of the bacterium to the skin is not well understood.[86–88] Keratinocyte differentiation promotes adherence of *S. pyogenes,*[86] whereas the primary epidermal cytokines tumor necrosis factor-α (TNF-α) and interleukin-1α (IL-1α) decrease adherence.[87] The hyaluronic acid capsule of *S. pyogenes* impedes adherence, and modulation of capsule expression may be important in the pathogenesis of skin infections.[88] The molecular interactions (i.e., bacterial adhesin and keratinocyte receptor) involved in initial attachment to the skin remain unknown. After attachment, invasion of *S. pyogenes* is related to numerous extracellular enzymes and toxins and membrane-bound proteins that function as virulence factors.[89,90]

Patients with streptococcal NSTIs can experience toxic shock-like syndrome that is associated with the streptococcal pyrogenic exotoxins A, B, and C.[91] These toxins and certain M-protein fragments appear to have the ability to interact simultaneously with the major histocompatibility complex (MHC) class II antigen on antigen-presenting cells and with specific Vβ regions of T-lymphocyte receptors, inducing massive synthesis and release of monokines, including TNF-α, IL-1β, IL-6, and the lymphokines TNF-β, IL-2, and interferon-γ.[73] These cytokines, particularly TNF, may in part mediate the rapid, massive tissue destruction seen in necrotizing fasciitis.[55]

Protease activity and production of Panton-Valentine leukocidin are postulated to correlate better with the ability of *S. aureus* to cause invasive disease and may be a mechanism for invasion of pyogenic bacteria from a cutaneous site.[62,63,92,93] A central feature of NSTI is vascular injury and thrombosis of the arteries and veins passing through the fascia.[56,74] A possible mechanism for the vascular injury leading to tissue ischemia and necrosis is greater adherence of neutrophils to vascular endothelium as a result of streptolysin O–induced upregulation of receptors.[94]

Clinical Presentation

NSTIs form a continuum, with some developing primarily in the more superficial layers of the subcutaneous tissues and others typically extending to the deep fascia and muscle. Although the rapidity and extent of tissue destruction and the causative agent vary, patients characteristically manifest few early cutaneous signs relative to the rapidity and extent of destruction of the subcutaneous tissues. Early clinical findings include ill-defined cutaneous erythema and edema that extends beyond the area of erythema. In some circumstances, the contiguous surface may be insensitive to pain or develop bullae. In contrast to the clinical findings of cellulitis, which may have a more distinct border, the patient with an NSTI has pain, tenderness, and constitutional signs that often are out of proportion to the cutaneous findings. This is particularly true with involvement of the deeper tissues, such as deep fascia and muscle.

Patients with involvement of the superficial or deep fascia or muscle tend to be more acutely and systemically ill and have more rapidly advancing disease than those with infection confined to subcutaneous tissues above the fascia. Other cutaneous signs, such as vesiculation, bullae formation, ecchymoses, crepitus, anesthesia, and necrosis, are ominous indications of advanced disease.[85] As reported by Keeley and colleagues, predictors of mortality for patients with NSTIs include bandemia; elevated creatinine, low bicarbonate, and elevated lactate levels; a lower admission temperature; and a shorter duration of presenting symptoms.[86]

Diagnosis and Management

A strong clinical suspicion and careful attention to the presentation and history of progression are important for making an accurate diagnosis and instituting appropriate and timely therapy. Failure to recognize differences among these infections can lead to suboptimal therapy because the need for aggressive surgical intervention and optimal antibiotic therapy varies. The most important question is whether the soft tissue infection is necrotizing or nonnecrotizing; the former requires prompt surgical removal of all devitalized tissue in addition to antimicrobial therapy, whereas the latter responds to antibiotic therapy alone. A study of 334 pediatric patients with NSTIs reported that nonsurvivors had a longer time from admission to their first debridement. Similar to that reported in the adult literature, prompt surgical debridement is the most important intervention for necrotizing disease in children.[87]

If the distinction is in doubt, imaging studies can aid in the diagnosis. Plain radiographs can detect subcutaneous gas, but this tends to be a late finding and is not present in earlier stages of the disease. Computed tomography and magnetic resonance imaging, with or without enhancement, may help to identify increased thickness of the fascial layer that can be associated with NSTI. Although these studies tend to have a high sensitivity, their main limitation is that they lack specificity, and for this reason, they may not be adequate to confirm a diagnosis of NSTI.[88]

Incisional biopsy can help to diagnose early NSTI when the clinical picture is not diagnostic. These procedures, however, should not delay surgical exploration and intervention in the course of destructive or potentially fulminant infection. Ultimately, precise determination of the planes of tissue involved in the infection cannot be based on clinical palpation and must be made definitively in the operating room. NSTI is considered a surgical emergency that requires prompt recognition, hemodynamic support and fluid resuscitation, surgical debridement, and appropriate antibiotic coverage.[89]

The IDSA suggests antibiotic therapy (with pediatric dosing) according to the suspected type of infection (Table 74.2).[2] Antibiotic management should be continued until the patient no longer needs repeated surgical interventions, there is clinical improvement, and the patient has been afebrile for 48 to 72 hours.[59]

TABLE 74.2

Antibiotic Treatment of Necrotizing Infections of the Skin, Fascia, and Muscle

First-Line Antibiotic Agents	Agents for Patients With Severe Penicillin Hypersensitivity
MIXED INFECTION	
Piperacillin/tazobactam *plus* Vancomycin	Clindamycin *or* Metronidazole; *plus* Aminoglycoside *or* Fluoroquinolone
Imipenem-cilastatin	
Meropenem	
Ertapenem	
Cefotaxime *plus* Metronidazole *or* Clindamycin	
***STREPTOCOCCUS* SPP. INFECTION**	
Penicillin *plus* Clindamycin	Vancomycin *or* Linezolid *or* Quinupristin-dalfopristin *or* Daptomycin
***STAPHYLOCOCCUS AUREUS* INFECTION**	
Nafcillin *or* Oxacillin *or* Cefazolin *or* Vancomycin (for resistant strains) *or* Clindamycin	Vancomycin *or* Linezolid *or* Quinupristin-dalfopristin *or* Daptomycin
***CLOSTRIDIUM* INFECTION**	
Clindamycin *plus* Penicillin	

Modified from Stevens DL, Bisno AL, Chambers HF, et al. Practice guidelines for the diagnosis and management of skin and soft tissue infections: 2014 update by the Infectious Diseases Society of America. Clin Infect Dis 2014;59:e10–e52.

Some investigators advocate the use of hyperbaric oxygen as an adjuvant therapy for patients with NSTI. Unfortunately, the lack of adequate studies of hyperbaric oxygen in pediatric patients makes this recommendation less reliable.

Intravenous immunoglobulin (IVIG) has been used as adjuvant therapy in patients with NSTIs, predominantly in those caused by streptococci. IVIG is thought to halt the infectious and systemic inflammatory response by neutralizing destructive toxins.[90] Lack of prospective pediatric studies preclude recommending the use of IVIG in children, and few adult studies demonstrate a potential benefit for IVIG in NSTIs.

Myositis, Pyomyositis, and Necrotizing Fasciitis

C. Buddy Creech

Skin and soft tissue infections (SSTIs) are common in children. They usually are recognized easily and treated with few residual long-term problems. However, myositis, pyomyositis, and necrotizing fasciitis are soft tissue infections that can be difficult to diagnose in their early stages, and despite appropriate antibiotic therapy, they can be associated with substantial morbidity and mortality.

The epidemiology of SSTIs is evolving, and the incidence among children is increasing. Community-associated, methicillin-resistant *S. aureus* (CA-MRSA) first emerged among children in the 1990s. Since then, CA-MRSA has become the predominant cause of purulent SSTIs in the United States. Coincident with this epidemic, the incidence of pediatric ambulatory visits for SSTIs has almost tripled.[1] SSTIs can be atypical and more severe in immunocompromised children.[2]

Myositis

Myositis is inflammation of a muscle, typically a voluntary muscle, characterized by pain, tenderness, swelling, and weakness. Causes of myositis include infection, autoimmune conditions, genetic disorders, medications, electrolyte disturbances, and diseases of the endocrine system.[3] Infectious myositis can be caused by bacteria, fungi, parasites, and viruses (Table 75.1).[3]

TABLE 75.1

Common Infectious Causes of Myositis

Organism Group	Organisms
Gram-positive bacteria	*Staphylococcus aureus*
	Streptococcus pyogenes (group A streptococcus)
	Streptococcus (groups B, C, and G; *S. pneumoniae; S. anginosus*)
Gram-negative bacteria	*Aeromonas hydrophila*
	Citrobacter freundii
	Enterobacter spp.
	Escherichia coli
	Proteus spp.
	Pseudomonas spp.
	Salmonella spp.
	Vibrio vulnificus
Anaerobic bacteria	*Bacteroides* spp.
	Clostridium spp.
	Streptococcus spp. (anaerobic, e.g., *Peptostreptococcus*)
Mycobacterium spp.	*Mycobacterium tuberculosis*
Fungi	*Candida* spp.
Parasites	*Trachipleistophora*
	Plasmodium spp.
	Sarcocystis spp.
	Taenia solium
	Trichinella spp.
Viruses	Enteroviruses (coxsackievirus B and echovirus)
	Human immunodeficiency virus (HIV)
	Human T-lymphotropic virus type 1(HTLV-1)
	Influenza A and B viruses

Modified from Crum-Cianflone NF. Bacterial, fungal, parasitic, and viral myositis. Clin Microbiol Rev 2008;21:473–494.

The clinical course can be acute, subacute, or chronic. Although identification of the causative microbe requires specific diagnostic testing (e.g., cultures), some clinical findings suggest the general category of the agent. For example, bacterial myositis usually causes focal muscle infection, whereas viruses and parasites often cause generalized myalgias or multifocal myositis. Bacterial myositis often occurs in the setting of muscular injury, surgery, ischemia, or a foreign body.

Bacterial Myositis

Acute bacterial myositis, defined as a diffuse muscle infection without an intramuscular abscess, occurs less commonly than pyomyositis and psoas abscess formation. Compared with pyomyositis, myositis is more often seen in adults than children.

Staphylococcus aureus.

Although *S. aureus* myositis is uncommon, the incidence has increased among adults and children in recent years, largely due to the emergence of CA-MRSA.[4,5] In the United States, the USA300 clone of CA-MRSA accounts for most infections. It appears that virulence has evolved in this strain through the increased expression of core genome-encoded virulence determinants, such as the two-component exotoxins (e.g., LukAB, LukDE, α-hemolysin, phenol-soluble modulins) and acquisition of the phage-encoded Panton-Valentine leukocidin (PVL) genes. Each of these toxins impact disease progression in animal models of USA300 infection. The basis of virulence in other CA-MRSA epidemics is less well understood.[5–7]

Streptococcus pyogenes.

S. pyogenes (i.e., group A *Streptococcus* [GAS]) can cause myositis. The most severe form is necrotizing myositis (i.e., streptococcal myonecrosis or spontaneous streptococcal gangrenous myositis).

Cases typically occur among men and young adults. The disease usually occurs spontaneously without a history of penetrating trauma or underlying immunosuppression. The portal of entry often is unknown. Some cases begin with a sore throat, suggesting that pharyngitis might have led to bacteremia and seeding of the muscle, but most cases occur without an antecedent illness.

The clinical presentation includes an initial prodromal stage with flu-like symptoms, which may include rash and myalgia. This evolves to intense local muscle pain that is disproportionate to clinical findings and to local tense swelling and fever.[8] The course can evolve rapidly over several hours (Fig. 75.1).

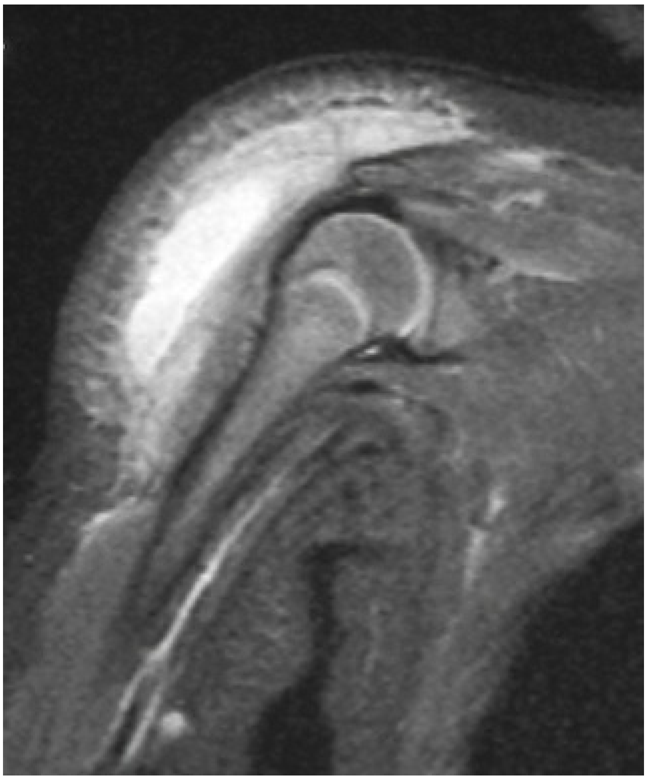

FIGURE 75.1 Necrotizing pyomyositis due to *Streptococcus pyogenes* in a 6-month-old infant with acute onset of fever, erythema, swelling, and pain of her right shoulder and decreased use of her arm. There was no break in the skin. Coronal fluid-attenuated inversion recovery (FLAIR) magnetic resonance imaging shows diffuse hyperintensity of the deltoid muscle with associated subcutaneous inflammatory stranding and edema. Osseous and fascial structures are normal. (Courtesy of E.N. Faerber and S.S. Long, St. Christopher's Hospital for Children, Philadelphia, PA.)

Clostridium Species.

Clostridial gas gangrene (i.e., myonecrosis) most commonly is caused by *Clostridium perfringens, C. novyi, C. histolyticum,* and *C. septicum*. *C. perfringens* is the most frequent cause of trauma-associated gas gangrene.[9] Infection occurs in a variety of settings: traumatic wounds with soil contamination, surgery involving the bowel or biliary system, septic abortions, vascular disease with arterial insufficiency, and injection of medications (e.g., epinephrine) or illicit drugs (e.g., heroin). Common inciting events include contamination of the site with *Clostridium* spp. (which exist in the soil and as part of the gastrointestinal flora of humans) and devitalized tissue. A foreign body is also a risk factor. In contrast to traumatic gas gangrene, spontaneous gangrene is principally associated with the more aerotolerant *C. septicum* and occurs predominantly in patients with underlying gastrointestinal conditions, including occult colon cancer, bowel infarction, or neutropenic enterocolitis.

C. septicum infections occur in children with three major predispositions: neutrophil dysfunction (e.g., malignancies, congenital or cyclic neutropenia, aplastic anemia), bowel ischemia (e.g., hemolytic uremic syndrome, intussusception), and trauma.[9] Malignancy underlies more than 50% of cases; acute myelocytic and lymphocytic leukemias are the most common. Cyclic and congenital neutropenia is identified in 20% of the published pediatric cases.

Clinical features associated with *C. septicum* infections in children include fever, vomiting, diarrhea, hematochezia, anorexia, and acute abdomen or distention. Despite treatment with surgery and parenteral antibiotics, mortality rates for children with *C. septicum* infections remain higher than 50%.[9]

Presenting symptoms of clostridial myonecrosis include intense pain, edema, and a sweet-smelling discharge that occur several hours to a few days after injury. The wound is initially pale but can evolve to a bronze color with hemorrhagic bullae. Classic findings include gas in the tissues detected by gas bubbles emitted from the wound or seen on radiographic films. Although gas often is considered to be essential for a diagnosis of gas gangrene, the absence of crepitus or gas on examination should not deter consideration of this diagnosis. Failure of the muscle to contract on stimulation and lack of bleeding of the wound during operation are characteristic findings.

Typical laboratory findings include leukocytosis and a hemolytic anemia due to clostridial α-toxin. Bacteremia occurs in 15% of cases. Gram stain evaluation of the wound exudate usually shows a lack of neutrophils and an abundance of gram-positive bacilli with blunt ends.

Nonclostridial Myositis.

Anaerobic streptococcal myositis has clinical characteristics similar to those of clostridial myonecrosis, including a foul, copious exudate, gas in infected tissues, and extensive necrosis of the involved muscles. Causes include anaerobic streptococci (e.g., *Peptostreptococcus* spp.), GAS, and *S. aureus*.

Synergistic nonclostridial myonecrosis is an infection of the subcutaneous tissues and fascia that can extend into the muscle. The infection often is polymicrobial, consisting of aerobic and anaerobic organisms such as streptococci (including *Peptostreptococcus* spp.), *Bacteroides* spp., *E. coli, Enterobacter* spp., and *Klebsiella* spp. *Aeromonas hydrophila* myonecrosis usually occurs after penetrating trauma in a freshwater environment or tissue injury associated with contact with aquatic animals. Progression can be rapid, and gas may form in the tissues.

Vibrio vulnificus is an opportunistic human pathogen that is lethal.[10] The bacterium is a part of the natural flora of coastal marine environments worldwide and has been isolated from water, sediments, and a variety of seafood. Of all *Vibrio* infections reported in the United States annually, 25% to 30% are nonfoodborne *Vibrio* infections (NFVIs).[11] *V. vulnificus* infections are the most common, accounting for 35% of NFVIs, and 72% of *V. vulnificus* infections are reported for residents of Gulf Coast states. SSTIs due to *V. vulnificus* result in amputation and death in 10% and 17% of cases, respectively.[11] Clinicians should consider *Vibrio* species as an etiologic agent in infections occurring in persons with recent seawater exposure, even if the individual was exposed only during recreational activities.

Other Forms of Bacterial Myositis.

Lyme disease can cause localized myositis of the orbit and other sites, often near areas of erythema migrans or joint involvement.[12] *Mycobacterium* spp. cause myositis by direct extension from a contiguous source such as an infected joint, bone, or abscess or, less commonly, from bacteremia. The most common site is a tuberculous psoas muscle abscess that forms by extension from vertebral osteomyelitis (i.e., Pott disease). Other examples include involvement of the intercostal muscles through extension from the lung or striated muscles of the leg through extension from the knee.

Fungal Myositis

Fungal myositis is uncommon. Most cases occur in immunocompromised patients. Fungal myositis can be caused by *Candida* spp. (most common), *Cryptococcus neoformans, Histoplasma capsulatum, Coccidioides* spp., *Aspergillus* spp., *Pneumocystis jirovecii,* and *Fusarium* spp. Biopsy with culture usually is required to confirm the diagnosis. The diagnosis often is not considered initially and is confirmed by histopathology or culture of muscle tissue.

Parasitic Myositis

A variety of parasites can encyst in muscle. The most common are *Trichinella* spp. (i.e., trichinosis), *Taenia solium* (i.e., cysticercosis), and *Toxoplasma gondii* (i.e., toxoplasmosis). The finding of eosinophilia and a history of travel to an endemic area suggest a possible parasitic cause of myositis.

Infection with *Trichinella spiralis* occurs after ingestion of larval cysts in undercooked pork or the meat of certain wild carnivores. The adult worm develops in the gastrointestinal tract and releases larvae that circulate through lymphatics and the bloodstream to striated muscle, where they become encysted and survive for several years. Most infections are subclinical. Autopsies reveal *Trichinella* cysts in more than 4% of randomly selected diaphragms.[13] Typical manifestations of symptomatic disease include fever, extreme malaise, muscle pain, weakness, and periorbital edema.[14] Serum muscle enzyme levels are elevated, and the patient has eosinophilia. Serodiagnostic testing is available and can preclude the need for biopsy. Most mild cases respond to analgesic therapy. In severe cases, anthelmintic therapy with thiabendazole or mebendazole is effective.[15]

After ingestion of eggs of the pork tapeworm *Taenia solium,* larvae migrate to excyst in skeletal muscle, leading to granulomatous nodules and calcific densities. Although fever, myalgia, and eosinophilia can occur, most cases of muscular cysticercosis, except those involving extraocular muscles, are asymptomatic. For infections that involve extraocular muscles, treatment with albendazole plus a corticosteroid or surgical removal of the encysted parasites may be necessary to preserve vision.[16–18]

During acute *Toxoplasma gondii* infection, tachyzoites can be widely disseminated, and skeletal muscle frequently is infected. Most cases of acquired toxoplasmosis are asymptomatic, although some patients experience a mononucleosis-like syndrome with nonspecific myalgia. Chronic inflammatory myositis associated with *T. gondii* has been reported in human immunodeficiency virus type 1 (HIV-1)–infected and other immunocompromised people.[19] Weakness, muscle wasting, and high serum levels of creatine kinase are characteristic features. Infection in the acute phase may be responsive to pyrimethamine plus sulfadiazine, whereas in the chronic phase, corticosteroid therapy may be beneficial.[20]

Viral Myositis

Many viruses can cause myalgias, polymyositis, or virus-associated rhabdomyolysis. The symptoms of myositis often are diffuse in nature, and patients have other symptoms and signs attributable to the causative viral pathogen. Influenza A and B viruses are the most commonly reported causes of viral myositis. Enteroviruses, human immunodeficiency virus (HIV), human T-cell leukemia-lymphoma virus type 1 (HTLV-1), and hepatitis viruses B and C also can cause myositis.

Influenza-associated myositis (IAM) has been reported only sporadically since its first description in 1957. IAM appears to be more common among children than adults, but its age-specific incidence during influenza epidemics is unknown.[21] IAM in children is characterized by severe lower extremity myalgia and a reluctance to walk.

Because IAM is associated with the influenza B virus, incidence may depend on circulating strains during an epidemic. During one European influenza B season, 219 children with IAM were studied; the median age was 7 years, and 74% were male.[22] IAM typically occurs with a 2 : 1 male predominance among children younger than 14 years and is characterized by an abrupt onset of severe myalgia in calf muscles, inability to walk, and elevated serum creatine kinase levels, usually within 1 week of influenza onset, when respiratory symptoms are improving.

Although the link between influenza and IAM is clearly established, its pathogenesis is not well understood. Two proposed mechanisms are viral invasion of muscle tissue and immune-mediated muscle damage triggered by the respiratory tract infection. Treatment is symptomatic because myositis is self-limited and usually resolves within a mean of 3 days (range, 1 to 30 days).

Influenza virus–associated rhabdomyolysis has been described in children and adults. Rhabdomyolysis is associated more frequently with influenza type A than type B and occurs more frequently in girls. The 2009 pandemic triple-reassortant influenza A (H1N1) virus was associated with neurologic and muscular syndromes that affected primarily children and included myositis.[23] Rhabdomyolysis can be complicated by renal failure and development of a compartment syndrome.

Enteroviruses, including coxsackieviruses (i.e., group A and B) and enteric cytopathogenic human orphan viruses (i.e., echoviruses), also cause myositis. Coxsackievirus B infection manifesting as pleurodynia is most common. Children typically are infected in the summer or fall and come to medical attention with paroxysms of severe, sharp chest pain. The costochondral muscles may be tender on palpation. In addition to pleurodynia, cases of rhabdomyolysis due to coxsackieviruses and echoviruses have been reported. The pathogenesis of myositis is uncertain, but muscle biopsies have shown degenerative necrosis of the muscle fibers and picornavirus-like structures. Therapy is symptomatic, and the disease usually resolves in several days. Recurrences of pleurodynia have been described in up to one fourth of cases.

HIV infection can cause a wide range of skeletal disorders, including myopathy, polymyositis, and rhabdomyolysis. Generalized myalgia, proximal muscle weakness, and elevated serum creatine kinase levels are common.[24] Muscle biopsy shows lymphocytic infiltration and necrosis of muscle fibers. These histologic findings are distinct from the mitochondrial myopathy associated with extended zidovudine therapy.[25] Although one study showed that proviral DNA could be detected in myocytes and muscle macrophages by polymerase chain reaction,[26] other researchers concluded that the disease probably represented a dysfunctional T lymphocyte–mediated process.[27] Corticosteroid therapy may be beneficial.[28]

Chronic Inflammatory Myositis

Several parasites and other pathogens can cause a chronic inflammatory reaction in skeletal muscle. In these disorders, persistence of the infectious agent appears necessary to cause chronic myopathy by direct tissue damage or as a consequence of the normal immunologic response to the infected tissue. In other disorders, such as juvenile dermatomyositis (JDM) and polymyositis, immunologic dysregulation is the hypothesized mechanism of disease.[29]

JDM is the most common form of pediatric idiopathic inflammatory myopathy, with an incidence ranging from 1.9 to 3.2 cases per million children.[30,31] The two major clinical features of JDM are a characteristic rash and symmetric proximal muscle weakness.[32] The gastrointestinal tract and lung often are involved.[32] Compared with the adult form of the disease, JDM more frequently has vasculitis features, skin ulceration, and calcinosis.[33] Patients with JDM often have a flu-like illness approximately 3 months before onset of the disease.

Coxsackievirus B and other enteroviruses are the most frequent infectious agents temporally associated with the onset of JDM.[34–37] Coxsackievirus B1 can induce chronic myositis of the proximal hind limbs in a murine model.[38] Serologic responses consistent with acute coxsackievirus B infection were found in patients in some studies[34] but not in others.[39] Although picornavirus-like particles have been observed on electron-microscopic examination of muscle biopsy samples from some children with JDM, immunofluorescence, polymerase chain reaction,[40] in situ nucleotide hybridization,[41] and tissue culture[36] have failed to identify a virus.

If an infectious agent precipitates JDM, it is hypothesized that immunologically mediated injury (possibly through molecular mimicry) rather than direct infection is the mechanism of injury. This pathogenic mechanism is supported by gene expression profile analyses of untreated JDM muscle biopsies, demonstrating an intense interferon α/β-induced response typical of that seen during an immune response to a viral antigen.[42]

Several reports have demonstrated an association between the human leukocyte antigen (HLA)-DQA1*0501 and JDM.[42–44] This association has been linked to an enhanced cytokine response partly contributed to by the tumor necrosis factor-α (TNF-α)-308A allele,[42,45] which is known to promote TNF-α synthesis. Enhanced TNF-α production was demonstrable in the circulation[45] and in muscle biopsies[46] from untreated JDM patients positive for the TNF-α-308A allele. This allele has been shown to be associated with pathologic calcifications and disease chronicity.[45,47] The pathogenesis of JDM after group A streptococcal infection may involve cytotoxic and cytokine responses elicited by specific epitopes of the streptococcal M-protein homologues of human skeletal myosin.[48]

Pyomyositis

Pyomyositis is an acute intramuscular infection due to hematogenous spread of the microorganism into the body of a skeletal muscle. By definition, it is not caused by a contiguous infection of the soft tissue or bone or by penetrating trauma. Pyomyositis has a predilection for large-muscle groups and often results in localized abscess formation.

Pyomyositis often is called *tropical myositis* because of its prevalence in tropical areas, where pyomyositis accounts for 3% to 5% of hospital admissions.[49–51] The first case of tropical pyomyositis from a temperate region was reported in 1971.[52] Since then, many cases have been reported from various parts of the world.[53–55] In North America, the highest incidence of pyomyositis is in southern regions.[56] Pyomyositis occurs most often in children and young adults,[57,58] exhibits a 2 : 1 male preponderance, and has occurred in the neonatal period.[59]

Methicillin-susceptible *S. aureus* (MSSA) was isolated from the purulent material in approximately 90% of cases in tropical areas and 75% of cases from temperate countries before the 1990s.[53] CA-MRSA (particularly the USA300 clone) has since emerged as a dominant cause in temperate climates.[60] Group A *Streptococcus* accounts for 1% to 5% of cases. Other causes include streptococci (i.e., groups B, C, and G), *E. coli, Citrobacter freundii, Serratia marcescens, Yersinia enterocolitica, Klebsiella* spp., and *Salmonella* spp. Individuals infected with HIV-1 are at increased risk for bacterial pyomyositis, sometimes with multifocal involvement.[61]

Staphylococcal pyomyositis most frequently affects the quadriceps, hamstring, or gluteal muscles but also can affect the paraspinous, shoulder girdle, psoas, and other muscles.[55] Symptoms usually begin insidiously, with low-grade fever, muscle aches, and cramping evolving over several days. Abscesses are multiple in about 25% of patients. In the early stages, examination may reveal only a rubbery firmness to the muscle belly, with no other superficial signs of inflammation. Within days to weeks, boggy swelling, erythema, tenderness, and warmth appear, and the lesion becomes fluctuant. Although substantial muscle destruction can develop with delayed treatment, serum levels of muscle enzymes usually are normal. Pyomyositis occasionally is complicated by metastatic infection such as empyema, pericarditis, or lung abscess. In rare cases, fulminant septicemia or toxic shock syndrome occurs.[62]

Pyogenic abscess in the psoas muscle produces a distinct clinical syndrome with lower abdominal or back pain radiating to the hip.[63] The febrile child may limp or hold the hip in fixed flexion because of muscle spasm. Confusion with pyogenic arthritis is common. Pain on hyperextension or abduction of the hip is elicited on examination. *S. aureus* is the most common cause, but psoas abscesses occasionally can develop as an extension of an abdominal process such as a ruptured appendix.[63] In such cases, a mixed infection with anaerobic and facultative bowel flora is likely.

Group A streptococci are an increasingly important cause of pyomyositis.[64,65] GAS infection of skeletal muscle can manifest as a localized phlegmon, an abscess, or more fulminant necrotizing myositis.[66,67] Intense pain is the most common presenting symptom, often out of proportion to clinical signs of inflammation. The child may refuse to bear weight or to move an extremity. Ultimately, high fever, localized swelling, and overlying erythema are observed. Tachycardia, hypotension, oliguria, confusion, lethargy, and scarlatiniform eruptions are early signs of associated streptococcal toxic shock syndrome. Mild to moderate leukocytosis with immature neutrophils (often >50%) and elevation of blood urea nitrogen, creatinine, and creatine kinase levels are common.[8]

Although a portal of entry is not always evident, the exanthem of primary varicella and various forms of minor skin trauma are important predisposing factors for GAS deep tissue infection in children. A prospective, population-based active surveillance for pediatric invasive GAS disease in Ontario revealed that varicella-zoster virus infection was associated with a 58-fold increased risk of invasive GAS disease among children.[64] Although the attack rate of invasive GAS was relatively low (5.2 cases/100,000 children), 15% of all pediatric invasive GAS infections, including 50% of cases of necrotizing fasciitis, followed varicella infection.

Necrotizing Fasciitis

Necrotizing fasciitis (i.e., hospital gangrene or hemolytic streptococcal gangrene) was described as early as the fifth century BC by Hippocrates.[68] Necrotizing fasciitis is a rapidly progressive, deep-seated bacterial infection of the subcutaneous soft tissue that can involve any area of the body. The course often is fulminant, with mortality rates ranging from 25% to 75%.[69,70] Many terms have been used to describe necrotizing soft tissue infections. A simplified classification is provided in Table 75.2.

TABLE 75.2

Necrotizing Infections of the Soft Tissues

Type	Usual Etiologic Agent	Predisposing Causes	Clinical Manifestations
Meleney synergistic gangrene	*Staphylococcus aureus,* microaerophilic streptococci	Surgery	Slowly expanding ulceration confined to superficial fascia
Clostridial cellulitis	*Clostridium perfringens*	Local trauma or surgery	Gas in skin, fascial sparing, little systemic toxicity
Nonclostridial anaerobic cellulitis	Mixed aerobes and anaerobes	Diabetes mellitus	Gas in tissues
Gas gangrene	Clostridial species (*C. perfringens, C. histolyticum,* or *C. septicum*)	Trauma, crush injuries, epinephrine injections; spontaneous cases related to cancer, neutropenia, cancer chemotherapy	Myonecrosis, gas in tissues, systemic toxicity, shock
Necrotizing fasciitis type 1	Mixed anaerobes, gram-negative aerobic bacilli, enterococci	Surgery, diabetes mellitus, peripheral vascular disease	Destruction of fat and fascia; skin may be spared; involvement of perineal area in Fournier gangrene
Necrotizing fasciitis type 2	Group A *Streptococcus*	Penetrating injuries, surgical procedures, varicella, burns, minor cuts, trauma	Systemic toxicity, severe local pain, rapidly extending necrosis of subcutaneous tissues and skin; gangrene, shock, multiorgan failure

Modified from Bisno AL, Stevens DL. Streptococcal infections of skin and soft tissues. N Engl J Med 1996;334:240–245.

Although more than 500 cases of necrotizing fasciitis have been reported in North America, it is an uncommon disease, and the true incidence is not known.[71,72] Males are affected slightly more commonly than females.[69,70,73] An increased frequency is associated with diabetes mellitus, intravenous drug use, chronic alcohol consumption, immunosuppression, and peripheral vascular disease.[70,71,73] Necrotizing fasciitis also occurs in young, previously healthy children and adults, for whom mortality rates are lower than among the elderly and those with underlying disease.[71]

Patients may report a history of recent surgery, trauma, eczema, or varicella infection.[69,74,75] Other precipitating factors include insect bites, perirectal abscess, incarcerated hernia, and subcutaneous insulin injection. Necrotizing fasciitis commonly is reported as a complication of varicella infection.[71,74,76] Necrotizing fasciitis also can occur after GAS pharyngitis or without any previous evidence of trauma or infection. The purported association between the use of nonsteroidal anti-inflammatory drugs and necrotizing fasciitis was not supported definitively by a prospective, multicenter, case-control study carried out among children hospitalized with primary varicella complicated by invasive GAS infection or necrotizing soft tissue infection.[74,77–79] In neonates, necrotizing fasciitis can complicate omphalitis or circumcision.

Necrotizing fasciitis often is classified as three types. The polymicrobial form of the disease is described as necrotizing fasciitis type 1, and it often occurs postoperatively or in patients with diabetes mellitus or peripheral vascular disease.[69,70,80] Pathogens include gram-negative bacilli, enterococci, streptococci, *S. aureus*, and anaerobes include *Bacteroides* spp., *Peptostreptococcus* spp., and *Clostridium* spp. (see Table 75.2). Necrotizing fasciitis type 2 is caused by GAS infection that can occur postoperatively or as a result of penetrating trauma, varicella infection, burns, or minor cuts; and it is characterized by rapidly extending necrosis and severe systemic toxicity. Type 2 disease is the most common form of necrotizing fasciitis in children.[71,73,81] Necrotizing fasciitis type 3 is rare and is caused by marine *Vibrio* spp., which enter through skin lesions that have been exposed to seawater or marine animals.

In children, necrotizing fasciitis often occurs 1 to 4 days after trauma, with soft tissue swelling and pain over the affected area.

Patients may appear well at initial presentation. When associated with varicella, the findings typically begin 3 to 4 days after onset of the exanthem.[75] Infants and toddlers may be fussy or irritable. Toddlers and young children may limp or refuse to bear weight. Initially, pain with manipulation of the affected extremity often is out of proportion to the cutaneous signs of infection.

Induration and edema usually are apparent within the first 24 hours and are followed rapidly by blistering and bleb formation.[65,76,82] Infection spreads in the plane between the subcutaneous tissue and the superficial muscle fascia, which results in progressive destruction of fascia and fat (Fig. 75.2). Pain and tenderness in the subcutaneous space are exquisite, but destruction of the nerves that innervate the skin eventually can lead to anesthesia of the overlying skin. The rapidly progressing infection can lead to toxic shock syndrome and severe systemic toxicity, including renal and hepatic failure, acute respiratory distress syndrome, and decreased myocardial contractility.

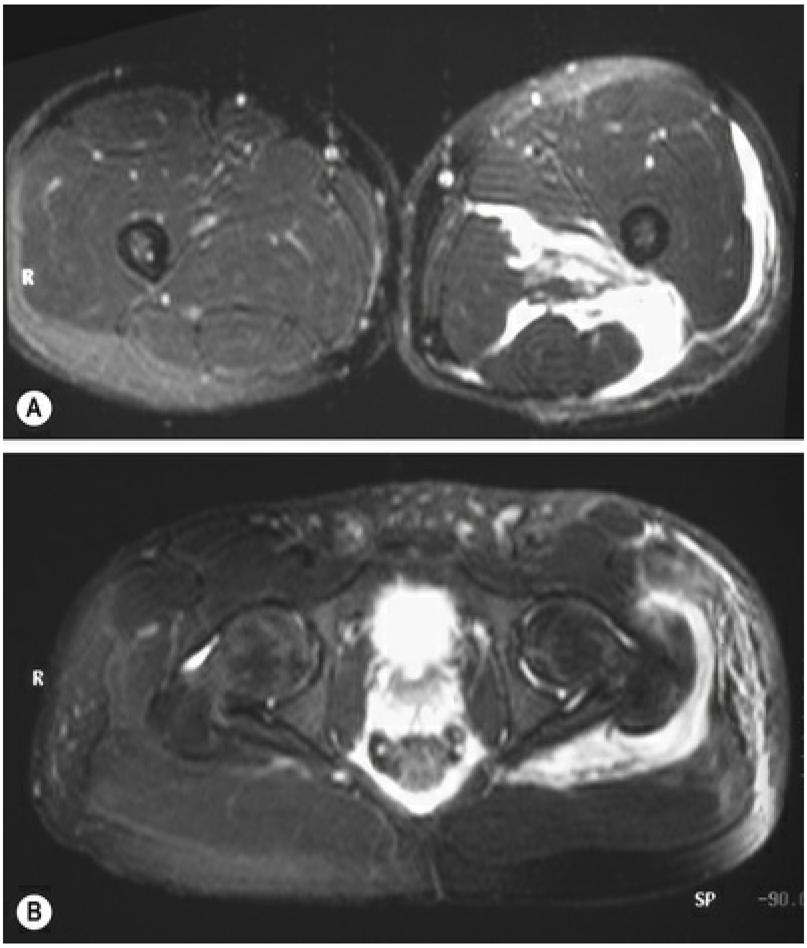

FIGURE 75.2 Pyomyositis and necrotizing fasciitis due to methicillin-resistant *Staphylococcus aureus* in a 17-year-old boy with a 1-day history of fever, poor appetite, and left hip pain, precluding ambulation. Physical examination showed fullness and exquisite tenderness of the buttock and posterior thigh without a break in the skin or erythema. (A and B) Axial T2-weighted magnetic resonance imaging shows hyperintensity of the fascia surrounding the tensor fascia lata and biceps femoris muscles from midthigh to the pelvic girdle. Surgery revealed necrotizing fasciitis. (Courtesy of E.N. Faerber and S.S. Long, St. Christopher's Hospital for Children, Philadelphia, PA.)

Extension of the infection along fascial planes leads to necrosis of the superficial fascia and the deeper layers of the dermis. Destruction and thrombosis of the small blood vessels in the area lead to necrosis of the surrounding tissues. The extensive tissue damage often leads to systemic symptoms, including multiorgan failure and shock.

Although white blood cell counts can be normal or elevated, there often is a pronounced shift to immature neutrophils. Thrombocytopenia and coagulopathy can occur. Attempts to identify causative organisms should be made through collection of anaerobic and aerobic blood cultures.[70,76] Cultures of the wound and surgically debrided tissue should be obtained. Frozen section biopsies can be helpful in making a timely diagnosis.

Pathogenesis

Skeletal muscle tissue is intrinsically resistant to bacterial infections, likely due to sequestration by myoglobin of iron that is required for proliferating bacteria. Staphylococcal muscle infections appear to be a complication of transient bacteremia and typically develop without penetrating injury or another clear portal of entry. Blood cultures frequently are negative.[83] Muscular trauma, strain, or vigorous exercise may be predisposing factors.[56,84] The high prevalence of the disease in the tropics has led to speculation that in patients with migrating parasitic infections, such as toxocariasis, microscopic foci of necrotic muscle develop that predispose to bacterial seeding.[85] Alternatively, a viral infection can be the precipitant; ultrastructural studies of nonsuppurating lesions in some patients with tropical pyomyositis reveal intracellular particles and a lymphocytic infiltrate.[86]

Group A streptococcal infection of skeletal muscle can take the form of a localized phlegmon, an abscess, or more fulminant necrotizing myositis or fasciitis,[66,67] associated with septicemia and toxic shock syndrome. The association of invasive GAS with primary varicella infection may result from the full-thickness skin lesion of chickenpox serving as a portal of entry for the organism (Fig. 75.3).[76,87,88] Varicella also produces a transient immunologic derangement, predisposing to secondary bacterial infection. A potential mechanism underlying the association of blunt trauma and streptococcal myonecrosis was provided by Bryant and colleagues,[89] who reported that muscle injury resulted in increased cellular vimentin expression, which enhanced colonization of GAS at the site of injury.

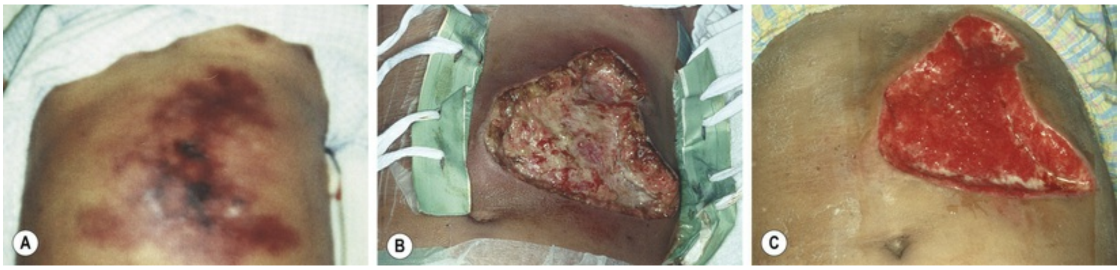

FIGURE 75.3 Necrotizing fasciitis of the abdominal wall due to *Streptococcus pyogenes* as a complication of chickenpox in a 7-year-old girl. (A) Notice the duskiness, ecchymosis, purpura, and edema of the abdominal wall. (B) There was full-thickness necrosis of skin, subcutaneous tissue, and fascia. (C) After multiple surgical debridements, the patient is ready for grafting. (Courtesy of J.H. Brien, ©.)

S. aureus and GAS express virulence factors, including adhesins, cytotoxins, superantigens, and immunomodulatory proteins, that contribute to the pathogenesis of infection. Although specific virulence factors are implicated in certain disease manifestations, such as superantigens as mediators of systemic toxicity and tissue injury,[90–92] no single virulence factor is sufficient to provoke a severe staphylococcal or streptococcal infection. Rather, a coordinated action of virulence factors is required for the bacteria to colonize successfully and spread within the host.[93–95] Tissue injury and systemic toxicity largely result from excessive inflammatory responses. A direct relationship between the magnitude of the inflammatory response and severity of invasive GAS infections has been demonstrated. Although GAS usually is considered an extracellular organism, macrophages can be a reservoir for GAS during acute deep tissue infections.[96] This may partially explain the persistent massive bacterial load despite adequate intravenous antibiotic therapy for a prolonged time in many patients.

Clostridium perfringens elaborates at least two exotoxins (i.e., α-toxin and perfringolysin O) that are cytolytic in host tissues and are lethal when purified and injected into animals.[97] *C. septicum* also expresses a pore-forming cytolysin, α-toxin, which triggers fulminant myonecrosis and inhibition of leukocyte influx into the lesion.[98] Exotoxin-induced microvascular dysfunction is an important factor producing the anaerobic environment that favors *C. perfringens* replication and ischemic necrosis.[39] In contrast, *C. septicum* is relatively aerotolerant, a feature that may partially explain its ability to spread through the bloodstream and establish infection in otherwise healthy muscle.[99]

Diagnosis

Early in the course, myositis, pyomyositis, or necrotizing fasciitis can be difficult to distinguish from a number of noninfectious disorders. Plain radiographs usually are normal, but other imaging techniques can be useful in defining the extent of muscle involvement. Although computed tomography (CT) may be useful in defining the extent of soft tissue involvement, magnetic resonance imaging (MRI) is the preferred imaging modality. MRI can reveal extension of inflammation along the fascial plains and distinguish the compartments and structures (e.g., bone, muscle, fascia, fat) involved (see Fig. 75.2).[100–102] Ultrasonography (US) is helpful in the suppurative phase.[100,103,104]

CT or US may delineate a low-density (or hypoechoic) fluid collection, facilitating diagnostic aspiration or percutaneous drainage.[105,106] Diagnostic MRI findings include hyperintense signal within the muscle with edema in pyomyositis and a hyperintense rim on unenhanced T1-weighted images and peripheral enhancement after intravenous infusion of gadolinium if an abscess has formed[101] (see Fig. 75.1). CT or MRI also can detect marked skeletal muscle abnormalities in GAS necrotizing myositis (Fig. 75.4).[106,107] Infrared thermography may help reveal the extent of tissue viability in clostridial myonecrosis.[108]

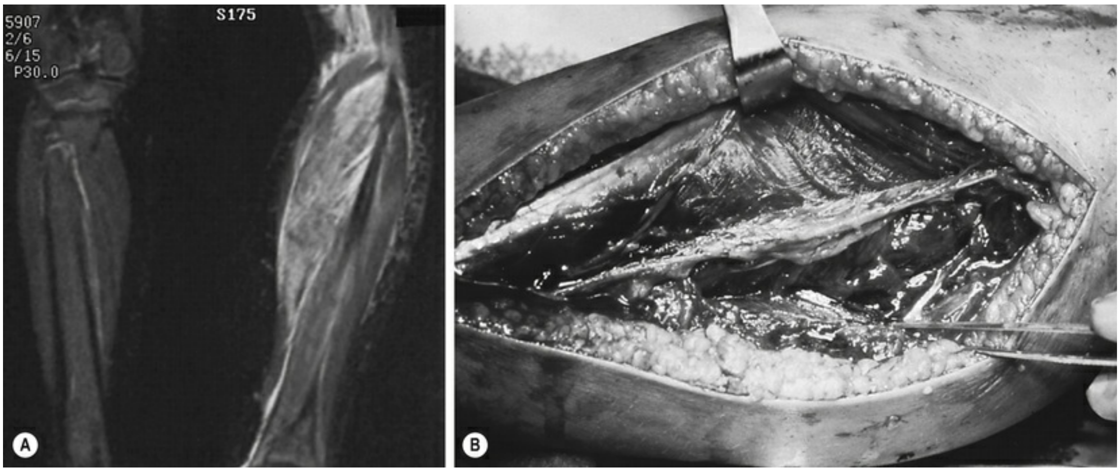

FIGURE 75.4 A 5-year-old girl had severe left posterior calf pain, tenderness, and swelling 1 week after onset of primary varicella. (A) With a magnetic resonance imaging technique in which the fat signal intensity is suppressed, marked signal enhancement is seen diffusely in the calf musculature, indicative of a widespread inflammatory process. (B) Operative exploration of the calf revealed liquefaction necrosis of the soleus muscle and the lateral head of the gastrocnemius muscle, which were radically debrided. Group A *Streptococcus* was isolated from the culture of tissue and blood. (Courtesy of J.H.T. Waldhausen, MD.)

Treatment

Therapeutic interventions for SSTIs include incision and drainage, debridement, compartment release, and antibiotic therapy. Recommendations from the Centers for Disease Control and Prevention[109] and the American Academy of Pediatrics[110] emphasize performing incision and drainage as the primary treatment of abscesses, submitting purulent material for culture, and targeting CA-MRSA when empiric antibiotics are prescribed (Table 75.3). Effective surgical drainage of fluid collections or abscesses often can be accomplished percutaneously with US or CT guidance,[111] but an open surgical procedure may be required.

TABLE 75.3

Antimicrobials for Treatment of Community-Acquired, Methicillin-Resistant *Staphylococcus aureus* Infections in Children

Antimicrobial	Daily Dosage
Daptomycin[a]	4–6 mg/kg/day q24hr
Linezolid	30 mg/kg/day divided q8hr (> or = 12 yr, 20 mg/kg/day divided q 12 hr, max 1.2 g/day divided q 12)
Vancomycin	40–60 mg/kg/day divided q6–8hr
Clindamycin	30 mg/kg/day divided q6–8 hr IV (max 4.8 g/day); 40–60 mg/kg/day divided q6–8hr PO (max 1.8 g/day)
Trimethoprim-sulfamethoxazole	20 mg/kg/day TMP divided q12hr

[a] Daptomycin should not be used to treat pneumonia. It is not approved by the US Food and Drug Administration for the treatment of children.

Surgical debridement usually is necessary for GAS necrotizing pyomyositis after the patient has been stabilized medically.[112] Fasciotomies are performed if there is evidence of increased compartment pressures. GAS uniformly is susceptible to penicillin and other β-lactam antibiotics, and penicillin remains an appropriate antibiotic treatment of GAS infections. However, in patients with aggressive GAS infections such as myositis and necrotizing fasciitis, a β-lactam antibiotic should be combined with clindamycin (40 mg/kg/day) because of its favorable pharmacodynamic properties and activity at the ribosomal level, inhibiting of toxin production.

Treatment of clostridial gas gangrene consists of prompt and radical debridement of involved muscles; amputation may be required. Because 5% of strains of *C. perfringens* are clindamycin resistant, the recommended antibiotic treatment is penicillin plus clindamycin.[113] Although the role of hyperbaric oxygen is controversial, therapy may serve an adjunctive role by retarding growth of *C. perfringens,* inhibiting α-toxin production, and increasing oxidative killing by host neutrophils.[114] Patients who survive may require amputation, skin grafting, or reconstructive surgery.

In severe GAS infections, the use of high-dose immune globulin intravenous (IGIV) has been proposed as adjunctive therapy. The mechanism of action of IGIV in this setting is thought to include inhibition of the superantigen activity through neutralizing antibodies, opsonization through M-specific antibodies, and a general anti-inflammatory effect.[115] Large controlled studies of IGIV therapy in patients with severe invasive GAS infections have not been conducted, but case reports and small controlled studies have reported on the uncontrolled outcomes of IGIV use in GAS toxic shock syndrome, necrotizing fasciitis, and necrotizing myositis (Table 75.4). Favorable results were reported for invasive GAS infections in an observational cohort study of Canadian patients identified through active surveillance[116] and in one European multicenter, placebo-controlled trial.[117]

TABLE 75.4

Intravenous Polyspecific Immunoglobulin as Adjunctive Therapy in Severe Invasive Group A Streptococcal Infections

Study Design	No. of Patients[a]	Case-Fatality Rate (%)
NF and myonecrosis, case series identified through active surveillance[118]	IGIV: 10	19
	No IGIV: 4	25
NF, case series identified through active surveillance[117]	IGIV: 10	10
	No IGIV: 67	37
Severe soft-tissue infections, observational cohort study[111]	7	0
STSS + NM, case report[119]	1	0
STSS + NF, case report[120]	1	0
STSS + NF, case report[121]	1	0
STSS + NF, case report[122]	1	0
STSS, case report[123]	1	0
STSS, case report[124]	1	0
STSS, case report[125]	1	0
STSS, case report[126]	1	0
STSS, case series[127]	5	20
STSS, multicenter placebo RCT[116,b]	IGIV: 10	10
	Placebo: 11	36
STSS, case-control study[115]	IGIV: 21	33
	No IGIV: 32	66

[a] All received IGIV unless otherwise specified.

[b] Trial prematurely terminated due to slow patient recruitment.[116]

IVIG, intravenous immunoglobulin; NF, necrotizing fasciitis; NM, necrotizing myositis; STSS, streptococcal toxic shock syndrome; RCT, randomized, controlled trial.

Data on the efficacy of IGIV for necrotizing fasciitis are limited (see Table 75.4).[112,118,119] In one study, the mortality rate was 10% for IGIV-treated patients, compared with 37% for untreated control subjects.[118] In an observational case study, the use of an aggressive medical regimen that included high-dose IGIV appeared to mitigate the need for aggressive surgical intervention.[82] Seven patients with severe GAS soft tissue infection (6 patients with toxic shock syndrome) were treated with antibiotics parenterally and high-dose IGIV; surgery was not performed or limited to exploration, and all patients survived. This limited study suggests that an initial conservative surgical approach combined with the use of immune modulators such as IGIV may reduce the morbidity associated with extensive surgical exploration in hemodynamically unstable patients.

Guidelines available online from the Infectious Diseases Society of America provide empiric therapeutic options for specific clinical scenarios (e.g., animal bites) and specific pathogens of SSTIs.[113]

76

Osteomyelitis

David K. Hong, Kathleen Gutierrez

Osteomyelitis is inflammation of bone. It usually is caused by bacteria but occasionally by fungi. Osteomyelitis in children has a mainly hematogenous origin; less commonly, it occurs as a result of trauma, surgery, or spread from infected contiguous soft tissue. Osteomyelitis due to vascular insufficiency is rare in children.

Acute Hematogenous Osteomyelitis

Pathogenesis

Acute hematogenous osteomyelitis (AHO) is primarily a disease of young children, presumably because of the rich vascular supply of their rapidly growing bones.[1–3] Infecting organisms enter the bone through the nutrient artery and then travel to the metaphyseal capillary loops, where they are deposited, replicate, and initiate an inflammatory response (Fig. 76.1). Metaphyseal localization results from sluggish blood flow, endothelial gaps in the tips of growing metaphyseal vessels, and lack of phagocytic cells lining the capillaries.[1–6] Bacteria proliferate, spread through vascular tunnels, and are anchored to areas of exposed cartilaginous matrix. Large colonies of bacteria surrounded by glycocalyx obstruct capillary lumens, impairing phagocytosis and antibiotic penetration.[7]

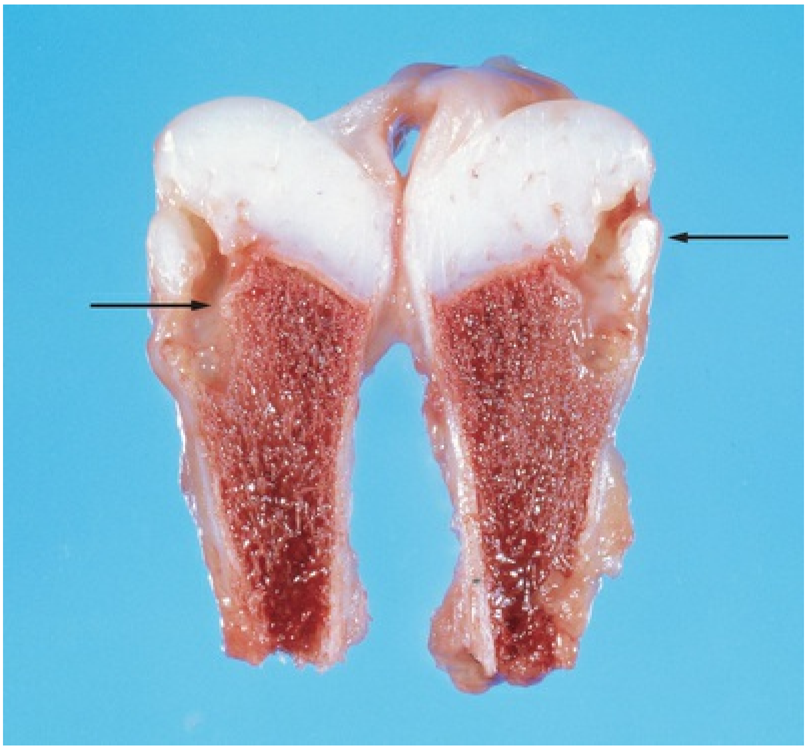

FIGURE 76.1 Gross specimen shows osteomyelitis of the proximal humerus in a 6-week-old infant. Notice the metaphyseal location and bony destruction *(arrows)*. (Courtesy of S.S. Long, St. Christopher's Hospital for Children, Philadelphia, PA.)

Age-related differences in the anatomy of the bone and its blood supply influence the clinical manifestations of osteomyelitis.[1,2] The transphyseal vessels, found in most children younger than 18 months, provide a vascular connection between the metaphysis and the epiphysis[1] (Fig. 76.2A). In infants, infection originating in the metaphysis can spread to the epiphysis and joint space. The risk of ischemic damage to the growth plate is greater in the young infant with osteomyelitis.[8] Before puberty, the periosteum is not firmly anchored to underlying bone. Infection in the metaphysis of a bone can spread to perforate the bony cortex, causing subperiosteal elevation and extension into surrounding soft tissue. Bony destruction also can spread to the diaphysis. By 2 years of age, the cartilaginous growth plate usually prevents extension of infection to the epiphysis and into the joint space. When the metaphysis of the proximal femur or humerus is involved, however, infection can extend into the hip or shoulder joint at any age, because the metaphysis is intracapsular at these sites (see Fig. 76.2B).

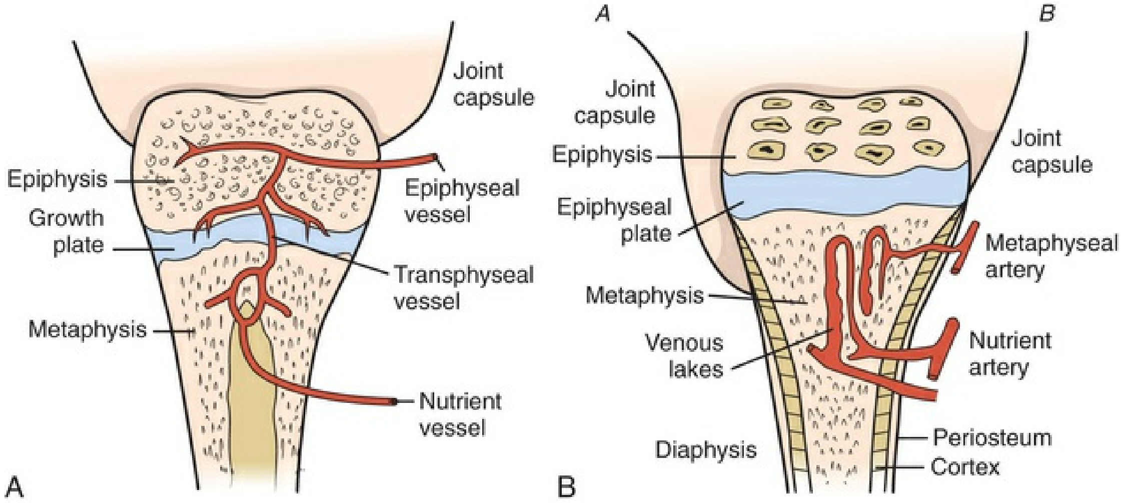

FIGURE 76.2 (A). Major structures of the bone of an infant before maturation of the epiphyseal growth plate. The transphyseal vessel connects the vascular supply of the epiphysis and metaphysis, facilitating the spread of infection between these two areas. (B) Major structures of the bone of a child. The joint capsule *A* inserts below the epiphyseal growth plate, as in the hip, elbow, ankle, and shoulder. Rupture of a metaphyseal abscess in these bones is likely to produce pyogenic arthritis. The joint capsule *B* inserts at the epiphyseal growth plate, as in other tubular bones. Rupture of a metaphyseal abscess in these bones is likely to lead to a subperiosteal abscess but seldom to an associated joint. (Modified from Gutman LT. Acute, subacute, and chronic osteomyelitis and pyogenic arthritis in children. Curr Probl Pediatr 1985;15:1–72.)

Histologic features of acute osteomyelitis include localized suppuration and abscess formation, with subsequent infarction and necrosis of bone. Segments of bone that lose blood supply and become separated from viable bone are called *sequestra.* An *involucrum* is a layer of living bone surrounding dead bone. A *Brodie abscess* is a subacute, well-demarcated focal infection, usually in the metaphysis but sometimes in the diaphysis of bone.[9]

Epidemiology

Approximately one half of AHO cases occur in the first 5 years of life.[10] Boys are affected twice as frequently as girls, except in the first year of life.[10,11] One third of patients have minor trauma to the affected extremity antecedent to infection, but the specific importance of this history is unclear, because virtually all young children experience frequent mild trauma.[12]

The relative risk of developing osteomyelitis appears to be higher in some populations. In one study, Polynesian and Maori children were more likely to develop complicated osteomyelitis with *Staphylococcus aureus* than other children in the same New Zealand community.[13] It is unclear whether genetic, socioeconomic, or environmental factors accounted for this difference.

Microbiology

S. aureus is the most common cause of AHO.[3,12,14–20] *Kingella kingae, Streptococcus pneumoniae,*[21] and *S. pyogenes*[22] are the organisms isolated in most other pediatric cases. *K. kingae* and *S. pneumoniae* infections are most common in children younger than 3 years of age. *S. pneumoniae* accounts for a relatively small proportion of infections, especially in the context of widespread immunization with the pneumococcal conjugate vaccine.[23,24] *K. kingae* can be associated with small outbreaks of bone and joint infections in childcare centers.[16,25] Coagulase-negative staphylococci (CoNS) (almost exclusively as a complication of medical intervention), enteric gram-negative bacilli, and anaerobic bacteria are uncommon etiologic agents.

Bartonella henselae can cause granulomatous infection of bone.[26–28] *Actinomyces* spp. cause facial and cervical osteomyelitis.[29] Infection with *Serratia* spp. and *Aspergillus* spp. should be considered in children with underlying chronic granulomatous disease.[30]

Before widespread use of *Haemophilus influenzae* type b (Hib) conjugate vaccine, Hib was the cause of 10% to 15% of cases of osteomyelitis in children younger than 3 years.[15,17] Hib is a rare cause in immunized children.[31]

Acute osteomyelitis due to community-acquired, methicillin-resistant *Staphylococcus aureus* (CA-MRSA) has become common.[32–34] Some CA-MRSA isolates causing osteoarticular infection carry the genes for Panton-Valentine leukocidin (PVL), a virulence factor or marker for complicated infections.[35,36]

Clinical Characteristics and Differential

Diagnosis

Most patients with AHO have symptoms for less than 2 weeks when they are brought to medical attention, although a small proportion have low-grade fever and intermittent bone pain for several weeks.[12,19] The most common manifestations are fever, pain at the site of infection, and reluctance to use an affected extremity.[15,37] Less common complaints are anorexia, malaise, and vomiting. Physical findings consist of focal swelling, tenderness, warmth, and erythema (usually over the metaphysis of a long bone). Rarely, a draining fistulous tract develops over the affected bone.[12]

Persistent tenderness during treatment of presumed soft tissue infection or cellulitis can be a clue to osteomyelitis. Exaggerated immobility of the joint and lack of point tenderness over the bony metaphysis suggest pyogenic arthritis. Other causes of bone pain are fracture, bone infarction due to hemoglobinopathy, leukemia, vitamin deficiency, and bony neoplasms such as metastatic neuroblastoma and Ewing sarcoma.

Osteomyelitis most frequently occurs in the long bones (Fig. 76.3), although in some series, 10% to 25% of cases involve short or nontubular flat bones, including the pelvis, vertebrae, clavicle, calcaneus, skull, ribs, and scapula.[15,19,38] Multiple bones are involved in about 5% of cases.

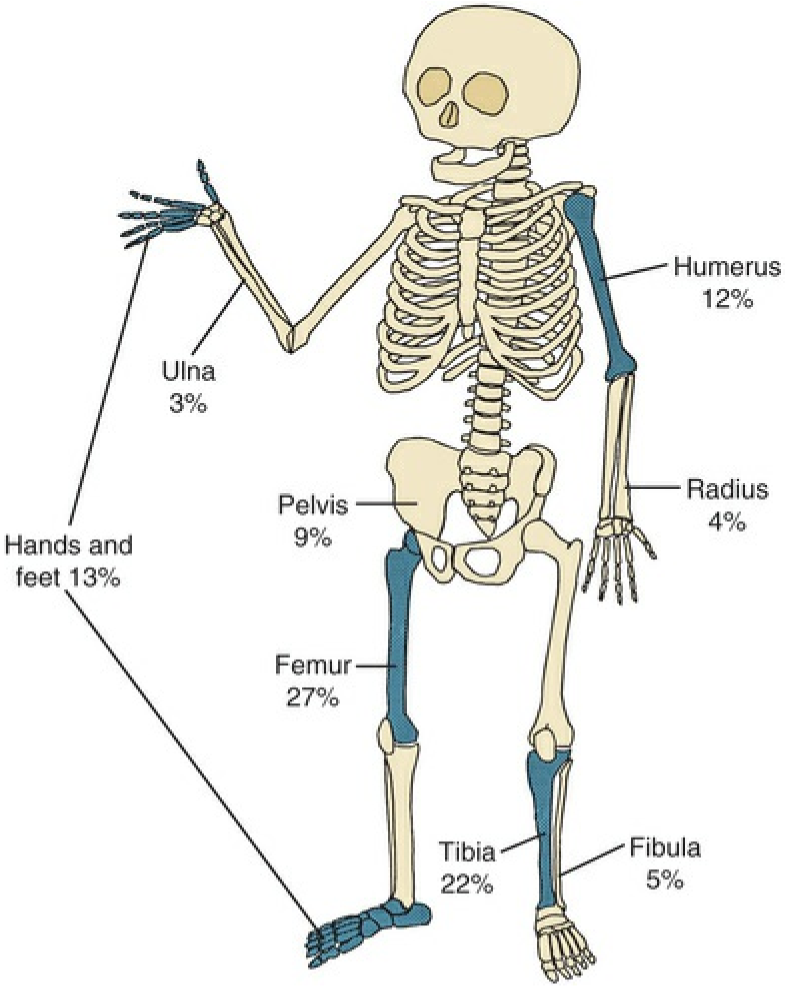

FIGURE 76.3 Sites of acute osteomyelitis in 657 children in whom a single bone was involved. *Shaded areas* constitute sites of approximately 75% of cases. Miscellaneous sites accounting for 5% are not shown.

(Data from references 11, 15, 19, and 37.)

Compared with methicillin-sensitive *S. aureus* (MSSA), patients with MRSA infections can have more protracted courses of fever, prolonged hospitalization, multiple foci of infection, pyomyositis, and subperiosteal and intraosseous abscesses.[35,39–41] Patients with PVL-positive CA-MRSA are at increased risk for deep vein thrombosis and septic emboli to the lungs.[36,40,42] PVL-positive isolates have not been associated with an increased likelihood of causing bone and joint infections.[43] However, compared with infection due to PVL-negative organisms, osteoarticular infections with PVL-positive *S. aureus*, whether MRSA or MSSA, appear to be associated with greater morbidity and are more likely to result in chronic osteomyelitis.[32,43,44]

Laboratory Diagnosis

Bacteriologic diagnosis can be confirmed in 50% to 80% of cases of AHO; bacteriologic confirmation is optimized when multiple specimens, including blood, bone, and joint fluid, are sampled.[2,11,12,15,19,37] Cultures obtained by imaging-guided bone biopsy are more likely to be positive if larger volumes (>2 mL) of purulent material are aspirated.[45] Diagnosis of *K. kingae* infection is enhanced with intraoperative inoculation of culture material directly into liquid media or onto agar plates.[46] The use of real-time polymerase chain reaction (PCR) testing has greatly enhanced the ability to detect *K. kingae*.[47]

The erythrocyte sedimentation rate (ESR) is elevated in up to 90% of cases of osteomyelitis, and the C-reactive protein (CRP) level is increased in 98%.[15,19,35,48] The mean ESR is 40 to 60 mm/hr, but levels greater than 100 mm/hr can occur. The ESR usually peaks 3 to 5 days after initiation of therapy and returns to normal in approximately 3 weeks. The CRP level peaks by the second day (mean, 8.3 mg/dL) of effective therapy and returns to normal (<2.0 mg/dL) after approximately 1 week of therapy.[48] Patients infected with PVL-positive instead of PVL-negative *S. aureus* are more likely to have positive blood culture results and higher ESR and CRP levels at presentation.[35] Higher levels of CRP at diagnosis may predict greater risk of sequelae.[49,50] The peripheral white blood cell count can be elevated or normal. Thrombocytosis can be remarkable, especially when symptoms exist for more than 1 week and persist during treatment.

Imaging Diagnosis

Plain Radiography

Radiographic abnormalities in osteomyelitis reflect inflammation of soft tissue and destruction and new formation of bone.[2,50,51] The earliest abnormalities, seen within the first 3 days of onset of symptoms, are deep soft tissue swelling and loss of the normally visible tissue planes around the affected bone. Osteopenia or osteolytic lesions from destruction of bone usually are not visible until approximately 50% of bone has been demineralized. Lytic lesions, periosteal elevation due to subcortical purulence, and periosteal new bone formation appear approximately 10 to 20 days after onset of symptoms. Sclerosis of bone is seen when infection has been present for longer than a month. If deep soft tissue swelling is seen on the plain radiograph of a patient with a short history of symptoms and with point tenderness over the affected metaphysis, no further imaging studies are necessary to support the diagnosis of osteomyelitis.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is the most accurate way of diagnosing osteomyelitis and offers enhanced sensitivity compared with plain radiography and radionuclide scanning.[52,53] The reported sensitivity of MRI for detection of osteomyelitis is 92% to 100%.

Normal red and fatty portions of the bone marrow have a characteristic appearance on MRI. Fatty marrow produces a bright signal on T1-weighted images.[54] Changes in marrow caused by infection and inflammation produce an area of low signal intensity within the bright fatty marrow. Areas of low signal intensity in infected marrow seen on a T1-weighted image are expected to show bright signal intensity on T2-weighted image. These changes are not specific for osteomyelitis and can be seen in cases of malignancy, fracture, and bone infarction. Major infection confined to the deep soft tissue can result in minor abnormality in adjacent bone.

MRI can detect signal alterations in soft tissue and is particularly useful in differentiating cellulitis from osteomyelitis. MRI also can aid differentiation of acute from chronic osteomyelitis.[55] Gadolinium-enhanced MRI can be particularly useful in the diagnosis of soft tissue, muscle, or bone abscesses.[41] The use of a contrast agent can increase confidence in the diagnosis of osteomyelitis in cases in which bone and soft tissue edema are seen on unenhanced images.[56] MRI has been used to identify bone marrow infection in cases of *B. henselae* infection, particularly when plain radiographs and computed tomography (CT) scans of the affected bones are normal.[27]

Radionuclide Scanning

Radionuclide scanning is useful in the early diagnosis of osteomyelitis, when plain radiographs are normal. A scan can be useful for patients who cannot undergo MRI due to medical devices (e.g., pacemakers) or braces. Radionuclide scans can be valuable when multifocal bone involvement is suspected[57] or when the site of infection cannot be localized, as in a toddler who refuses to bear weight. A technetium-labeled methylene diphosphonate isotope is most frequently used because its uptake by infected bone is enhanced when osteoblastic activity is increased.

The reported sensitivity of technetium-99 bone scanning is between 80% and 100% for patients studied from less than 6 weeks to 15 years of age.[58–62] The bone scan can be normal for 5% to 20% of children with osteomyelitis in the first few days of illness.[61,63–65]

Treatment

Antibiotic Choice

The choice of a specific antimicrobial regimen considers the age of the child, underlying medical conditions, suspected pathogens and their susceptibility pattern, antibiotic pharmacodynamics, and evidence of safety and efficacy.

Most β-lactam antibiotics achieve therapeutic concentrations in bone.[66,67] Clindamycin has particularly good bone penetration, attaining a high bone-to-serum ratio.[66,68,69] Vancomycin has excellent penetration into the bones of experimental animals. Aminoglycoside agents theoretically have poor bactericidal activity in bone because of local tissue hypoxia and acidosis. Although ciprofloxacin penetrates well into bone, fluoroquinolones are not recommended for use in young children.[70]

Most cases of AHO in any age group are caused by *S. aureus.* Empiric therapy should include coverage for MSSA with an agent such as parenterally administered nafcillin, clindamycin, or a first-generation cephalosporin, and in most cases, CA-MRSA. Clindamycin remains a good choice for empiric therapy in communities where less than 10% of MRSA isolates are resistant.[41] In communities where CA-MRSA resistance to clindamycin is greater than 10% to 15%, vancomycin should be considered in empiric therapy.[71] Clindamycin and vancomycin are active against most isolates of *S. pyogenes* and *S. pneumoniae.* Neither offers adequate coverage for *K. kingae* infection, which is susceptible to most β-lactam antibiotics. In children younger than 4 years of age, empiric antibiotic regimens should include coverage against *K. kingae*, as should definitive therapy if initial cultures are negative.[72] Ampicillin-sulbactam or a third-generation cephalosporin should be considered in addition to clindamycin or vancomycin in young children. Hib need not be covered in the fully immunized and immunocompetent child.

Neonates with osteomyelitis should be treated with antibiotics active against MSSA, MRSA, group B *Streptococcus* (GBS), and gram-negative enteric organisms. Suggested initial empiric parenteral antibiotic therapy for neonates and children with AHO is outlined in Table 76.1.

TABLE 76.1

Antibiotic Selection for Initial Treatment of Osteomyelitis

Patient	Likely Pathogen	Antibiotic	Dosage[d]	
			mg/kg per day	Divided Doses/Day
Neonates[a]	*Staphylococcus aureus*	Nafcillin	100	4
	Group B *Streptococcus*	*or*		
	Enteric gram-negative bacteria	Vancomycin	30	2
		plus		
		Gentamicin	4	1
		or		
		Cefotaxime	150	3
Infants and children	*Staphylococcus aureus*	Clindamycin[c]	30–40	3
	Streptococcus pyogenes	*or*		
	Kingella kingae[b]	Vancomycin (if ill-appearing)	45	3
		or		
		Cefazolin	100	3

[a] Dosing may need to be adjusted based on gestational age, postnatal age, and current weight.

[b] If the patient is treated with clindamycin or vancomycin, consider adding ampicillin, ampicillin-sulbactam, or cephalosporin for *Kingella kingae* in children younger than 4 years of age.

[c] If clindamycin resistance locally is >10%, use vancomycin for serious infections, and add cefazolin.

[d] Not to exceed adult dosing.

Antibiotic therapy should be modified according to the results of culture and susceptibility testing. Nafcillin, oxacillin, a first-generation cephalosporin, or clindamycin (if susceptible) are the drugs of choice for infections caused by MSSA. Clindamycin is a good definitive choice for susceptible MRSA without inducible resistance in vitro.[73–75]

There are few antibiotic choices for clindamycin-resistant CA-MRSA infection in children. Guidelines by the Infectious Disease Society of America (IDSA) recommend vancomycin with or without rifampin for the treatment of MRSA osteomyelitis in children. Linezolid is suggested as an alternative.[71] Limited data on the use of linezolid for osteoarticular infections in children suggest that it is safe and effective.[76,77] Linezolid has excellent oral bioavailability and offers an alternative to prolonged intravenous therapy. However, it is expensive, and many children object to the taste of the oral suspension. Long-term use has been associated with neutropenia, thrombocytopenia, and elevated serum transaminase levels.[78] Rare reports of lactic acidosis and optic neuropathy have been associated with linezolid therapy.[79,80]

Most CA-MRSA isolates are susceptible to trimethoprim-sulfamethoxazole, tetracyclines, and rifampin. Clinical experience with these drugs for osteoarticular infections is limited.[81,82] Rifampin should not be used as a single agent because of rapid development of resistance. Although daptomycin and tigecycline have activity against MRSA, neither is approved for use in children. The IDSA guideline suggests daptomycin use in children in selected circumstances.[71] If no organism is isolated, and the symptoms are resolving, initial empiric therapy should be continued. Most cases of culture-negative osteomyelitis respond to therapy with antistaphylococcal antibiotics, with the addition of therapy against *K. kingae* in younger children.

Management of children with osteomyelitis should include concurrent care by an orthopedic surgeon. Indications for surgery include unremitting fever, erythema, pain, and swelling; persistent bacteremia despite optimal antibiotic therapy; soft tissue or periosteal abscess; formation of a sinus tract; and necrotic, nonviable bone.[83]

Duration of Therapy and Transition to Oral Therapy

Duration of antibiotic therapy depends on the cause and extent of infection, adequacy of surgical debridement if required, and the clinical course and laboratory evidence of resolution. The usual duration ranges from 3 to 6 weeks, and treatment should be individualized on the basis of severity of illness and clinical response. Historical evidence suggests that less than 3 weeks of treatment is associated with higher rates of relapse or recurrence than longer duration of therapy.[12,84,85]

Most patients can be managed successfully with early transition from parenteral to oral antibiotics. Oral antibiotics appear to be equally effective as parenteral antibiotics in the posthospital discharge treatment of osteomyelitis.[86] Prolonged intravenous therapy through a peripherally inserted or tunneled central venous catheter (i.e., PICC or CVC) has been associated with substantial risk (15% in one study) of catheter-related complications, including catheter malfunction, thrombosis, and catheter-associated bloodstream infections.[86–88]

The change to oral antibiotics usually is made when fever, pain, and signs of local inflammation have resolved and laboratory values, especially the CRP level, are normalizing. The willingness of the child to take oral medication and the likelihood of adherence to the regimen also must be assessed. Bacteriologic confirmation greatly aids the choice of antibiotic. For unconfirmed bacteriology, the oral antibiotic should have the same spectrum of coverage as the parenteral drug. If a β-lactam agent is used, the usual dosage required is two to three times the usual oral dose (Table 76.2).

TABLE 76.2

Dosage of Antibiotics Commonly Used in the Oral Phase of Treatment of Osteomyelitis

Antibiotic[a]	Dosage[d]	
	mg/kg per day	Divided Doses/Day
Dicloxacillin	75–100	4
Cephalexin	100	3–4
Clindamycin	30–40[b]	3–4
Linezolid	20[c]	2

[a] The dose of β-lactam antibiotics used for osteomyelitis usually is two or three times the dose for skin and soft tissue infection.

[b] Clindamycin (40 mg/kg/day) is recommended for the treatment of susceptible

methicillin-resistant *Staphylococcus aureus* (MRSA) osteomyelitis.[71]

[c] Linezolid dosing for children younger than 12 years of age is 30 mg/kg/day (10 mg/kg/dose every 8 hours). The maximum dose is 600 mg.

[d] Not to exceed adult dosing.

When the change to oral therapy is made, the child should be monitored to ensure continued clinical improvement. The CRP level is expected to return to normal 7 to 10 days after initiation of appropriate therapy, and the ESR returns to normal within 3 to 4 weeks.[48,89]

Special Clinical Situations

Neonatal Osteomyelitis

Osteomyelitis is uncommon in the neonatal period. The incidence of hospital-associated osteomyelitis is approximately 1 to 3 cases for every 1000 admissions to the neonatal intensive care unit.[90]

Associated risk factors include prematurity, low birth weight, preceding infection, bacteremia, exchange transfusion, and an intravenous or umbilical catheter.[91–93] Osteomyelitis of the skull due to contiguous spread of infection has occurred as a complication of fetal scalp electrode monitoring[94] and in association with infected cephalohematoma.[95] Osteomyelitis of the calcaneus has complicated heel lancet puncture.[96]

The diagnosis of osteomyelitis in neonates often is delayed because of nonspecific symptoms and signs, which can include fever, irritability, swelling or decreased movement of a limb (i.e., pseudoparalysis), or erythema, or tenderness over the affected bone.[97] Preterm infants are more likely than term infants to have symptoms of septicemia.[98] Approximately 20% to 50% of neonates with osteomyelitis have infection of multiple bones,[90,99,100] and about 75% have suppurative arthritis of contiguous joints[100] (Fig. 76.4).

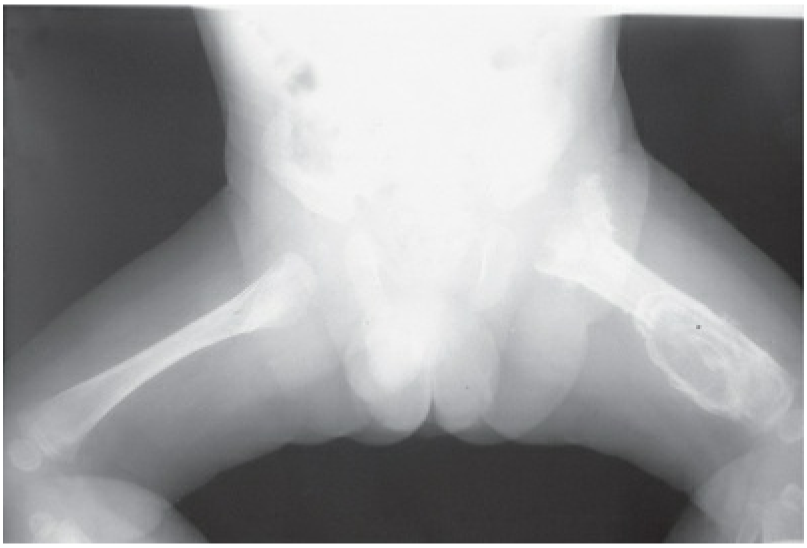

FIGURE 76.4 Plain radiograph of an infant at 2 months of age who had a *Staphylococcus aureus* bloodstream infection during a stay in the neonatal intensive care unit during the first month of life. He had multiple sites of infection, including the proximal and distal femur and hip joint. Notice the widespread destruction of the femur, acetabulum, and joint. (Courtesy of S.S. Long, St. Christopher's Hospital for Children, Philadelphia, PA.)

S. aureus (including CA-MRSA[101]) is the predominant etiologic agent, followed by GBS and enteric gram-negative bacilli, with increased relative importance of gram-negative bacilli and *Candida* species in nosocomial cases. Fungi,[102] *Ureaplasma urealyticum,*[103] CoNS,[104] *Neisseria gonorrhoeae,*[97] and anaerobic bacteria[105] are unusual causes.

Infants with bone infection caused by GBS usually have had an uncomplicated neonatal course and have infection of a single bone. There is a predilection for involvement of long bones on the right, particularly the right proximal humerus, which may be related to trauma during vaginal delivery.[104,106] Misdiagnosis of bone infection as trauma in these mildly ill infants is common.

The white blood cell count commonly is normal; ESR and CRP levels often are elevated.[107] In most infants, an osteolytic lesion is visible on plain radiographs 10 to 12 days after onset of symptoms (sometimes at the time of recognition).[108,109] The radionuclide bone scan result can be positive,[90] but it sometimes is less sensitive than a plain radiograph.

Neonatal osteomyelitis can cause permanent joint abnormalities or disturbance in skeletal growth due to damage to the cartilaginous growth plate, leading to chronic arthritis, decreased range of motion, limb length discrepancy, and gait abnormalities.[110] The reported incidence of permanent sequelae varies from 6% to 50%.[98,104]

Vertebral Osteomyelitis

Vertebral osteomyelitis accounts for approximately 1% to 3% of cases of osteomyelitis in children.[111,112] Boys are affected twice as often as girls.[113] Infection usually occurs as a result of hematogenous seeding of the vertebral bodies. Osteomyelitis also can result from extension of soft tissue infection or as a complication of a surgical procedure.[114]

Clinical manifestations can be indolent and nonspecific, leading to delayed diagnosis.[115] Young infants can have nonspecific signs of septicemia.[116] Symptoms in older children include back, chest, abdominal, or leg pain and loss of normal curvatures.[111,117] Rarely, children have dysphagia due to a paravertebral or retropharyngeal abscess or acute spinal cord paresis or paralysis from paraspinal compression. Fever is common, and there can be tenderness over the involved vertebrae. Neurologic deficits are found in 15% to 20% of cases.[111,113,115,118]

S. aureus is isolated in most cases.[111,113,119] In one review, *Salmonella* spp. caused 12% of cases of childhood vertebral osteomyelitis.[111] Gram-negative bacilli such as *Escherichia coli* cause vertebral osteomyelitis in adults, particularly those with a history of recent urinary tract infection or instrumentation. Vertebral osteomyelitis in intravenous drug users is commonly caused by *Pseudomonas aeruginosa* and less commonly by *S. aureus, Serratia* spp., *Klebsiella* spp., *Enterobacter* spp., or *Candida* spp.[113,120] Tuberculosis and brucellosis should be considered if symptoms and radiographs suggest chronic infection.[121,122]

Characteristic findings on plain radiographs consist of narrowing of the involved disk space, lucency of the adjacent vertebral bodies, and, eventually, reactive sclerosis of the bone with fusion of vertebral bodies.[20,111,119] Vertebral osteomyelitis is differentiated from diskitis radiographically by the minimal vertebral end plate involvement associated with diskitis. MRI is highly sensitive (96%) and specific (92%) for the diagnosis of vertebral osteomyelitis and paravertebral soft tissue extension[123,124] (Fig. 76.5).

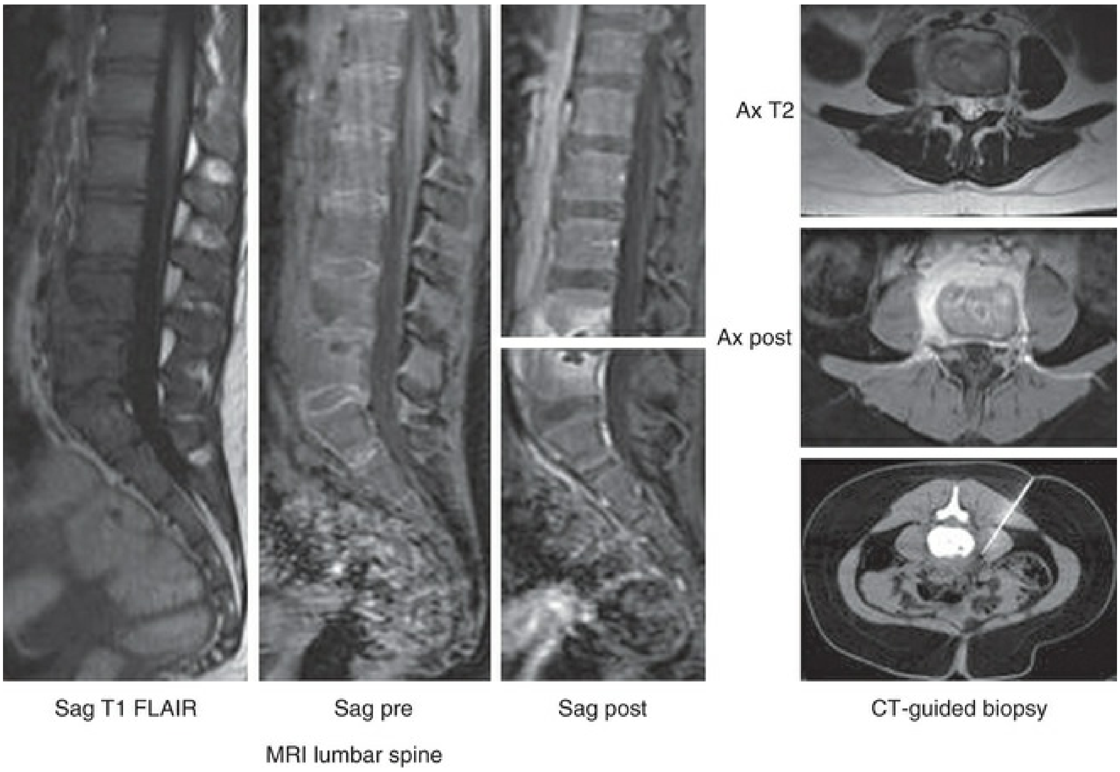

FIGURE 76.5 Sagittal and corresponding axial magnetic resonance imaging *(MRI)* of an adolescent girl who developed subacute, progressive back pain after returning from the Dominican Republic. Fluid attenuated inversion recovery *(FLAIR)* and the precontrast and postcontrast sequences show osteomyelitis of vertebral bodies lumbar 4 and 5 and a paraspinal abscess. The *lower right* image shows the computed tomography *(CT)*-guided site of aspiration, which yielded *Salmonella enterica* serotype Typhi. (Courtesy of S.S. Long and M. Mallon, St. Christopher's Hospital for Children, Philadelphia, PA.)

Blood culture results are positive in only about 30% of acute cases. When blood culture results are negative, obtaining an image-guided biopsy specimen or aspirate of bone or soft tissue phlegmon or abscess must be considered.[124]

Urgent drainage or surgical decompression and debridement are indicated for spinal epidural or paraspinal abscess, signs of spinal cord compression, or extensive bony destruction. Children with uncomplicated vertebral osteomyelitis and no evidence of abscess formation should be treated with at least 4 weeks of antibiotics.[111] In a randomized, controlled noninferiority trial enrolling 359 adults, therapy for 6 weeks was noninferior to that for 12 weeks.[125] Complications of vertebral osteomyelitis include neurologic deficits due to epidural or paravertebral abscess and infected aneurysms of the aorta.[126,128]

Pelvic Osteomyelitis

Approximately 6% to 9% of hematogenous osteomyelitis cases involve the bones of the pelvis.[38,129,130] The ilium and ischium are involved most commonly[129]; infection of the sacrum, acetabulum, or pubic symphysis is rare.[129–132] Risk factors can include a history of pelvic trauma, intravenous drug use, or a genitourinary procedure.[129,131]

Most patients with pelvic osteomyelitis have fever, gait abnormalities, and pain that is often localized to the hip, groin, or buttock.[132–135] Pain with hip movement and point tenderness over the affected bone often is observed. Clinical features can mimic those of pyogenic arthritis of the hip[129]; however, in pelvic osteomyelitis, there is more likely to be near-normal range of motion of the hip, absence of referred pain to the knee, specific point tenderness over the affected bone (or pain on rocking of the pelvic girdle), and abnormal rectal findings.[133] Responsible pathogens are similar to those that cause osteomyelitis of long bones.

Plain radiographs of the pelvis often are normal. MRI is the preferred imaging modality, and it has the additional advantage of differentiating osteomyelitis from infections of the muscles of the pelvic girdle. MRI also can identify abscesses associated with pelvic osteomyelitis, and CT can direct aspiration.[136] Aspiration, surgical drainage, or debridement should be considered in cases of extraosseous abscess formation or for patients whose symptoms do not respond to intravenous antibiotic therapy.

Patients should be treated for at least 4 weeks with antibiotics. Early transition to oral antibiotics can achieve resolution rates similar to those of prolonged intravenous antibiotics.[86,133]

Children With Sickle Hemoglobinopathies

Children with sickle cell disease have increased susceptibility to bacterial infections, including osteomyelitis.[137] The suspected pathogenesis is a primary microscopic infarction in the intestinal mucosa and bone, resulting in bacteremia and focal bone infection. Splenic hypofunction, impaired opsonization, impaired macrophage function, altered expression of proinflammatory and anti-inflammatory cytokines, microembolism, and tissue infarction are likely contributing factors in the development of osteomyelitis.[138,139]

Salmonella spp. and other gram-negative enteric bacilli were the cause of more than 70% of cases of osteomyelitis in children with hemoglobinopathies in past decades.[140–143] *S. aureus* currently is the dominant cause. Other organisms causing osteomyelitis in children with sickle hemoglobinopathies are listed in Box 76.1.

Box 76.1

Bacterial Causes of Osteomyelitis in Children With Sickle Cell Disease

Common

Staphylococcus aureus

Salmonella spp.

Less Common

Escherichia coli

Haemophilus influenzae

Shigella spp.

Streptococcus pneumoniae

Distinctive features of osteomyelitis in children with sickle cell disease are frequent involvement of the diaphyses of long bones, flat bones, and small bones of the hands and feet and multifocal, symmetric bone involvement.[144,145] Manifestations of osteomyelitis are difficult to differentiate from those of acute vaso-occlusive crisis. Fever, bone pain, and leukocytosis are common in both conditions. A temperature above 39°C, a toxic appearance, and an absolute band count greater than 500 cells/mm^3 are more consistent with infection, but there is considerable overlap in clinical and laboratory findings.[143]

Plain radiography, technetium scanning, CT, and MRI cannot differentiate infarction from infection.[145,146] If fever and bone pain have not improved after supportive care has been given for vaso-occlusive crisis, imaging-guided aspiration of the affected area of bone for Gram stain and culture should be performed.

Six to eight weeks of antibiotic therapy may be necessary for treatment of osteomyelitis in patients with sickle hemoglobinopathy because of the usual mixed infarction and infection. Oral therapy can be substituted for parenteral treatment when a pathogen has been confirmed, an appropriate oral agent is identified, and there is clinical improvement. Relapses, especially when due to *Salmonella*, can occur.[143,144]

Osteomyelitis Due to Unusual Organisms

Fungal Osteomyelitis

Fungal osteomyelitis, most frequently is caused by *Candida* spp. and is unusual in healthy children, but it does occur in prematurely born neonates (usually is a complication of device-associated infection), immunocompromised patients, and intravenous drug users.[102,47,148] *Aspergillus* spp. cause osteomyelitis in children with chronic granulomatous disease, often resulting from contiguous spread of pulmonary infection.[149] *Blastomyces dermatitidis, Coccidioides immitis, Histoplasma capsulatum,* and *Cryptococcus neoformans* cause osteomyelitis in indigenous geographic regions and in immunosuppressed hosts.[150–152]

Tuberculous Osteomyelitis

Skeletal lesions occur in approximately 1% of children with tuberculosis.[121,153] Bones and joints are infected through hematogenous or lymphatic dissemination of *Mycobacterium tuberculosis.* Infection can smolder for years before clinical signs are apparent. The most commonly involved bones are the vertebrae (i.e., tuberculous spondylitis), femur, long bones around knees and ankles, and small bones of the hands and feet.[154] Less frequently infected sites are the ribs, mandible, sternum, clavicle, and other long bones. Multifocal osteomyelitis is reported in 10% to 15% of cases.[155,156]

Clinical signs and symptoms of skeletal tuberculosis include low-grade fever, weight loss, pain, and soft tissue swelling at the site of infection. Vertebral involvement begins in the anterior vertebral body, eventually causing disk space collapse and anterior wedging of vertebral bodies, sometimes causing a gibbus deformity. The lower thoracic spine is the usual site of involvement (i.e., Pott disease), followed by the lumbar spine.

The Mantoux tuberculin skin reaction usually is positive. The role of interferon γ release assays in the diagnosis of Pott disease is being evaluated. Plain radiographic findings include periarticular osteopenia, lytic lesions in the body of the vertebra, joint space narrowing, and soft tissue swelling.[157] The chest radiograph often is normal. CT is useful for the evaluation of bone destruction, adjacent soft tissue abscess formation, and calcification and in guiding percutaneous biopsy.[158] MRI is helpful in determining the extent of bone and soft tissue disease.[159] Biopsy specimens should be obtained to demonstrate the organism with stains and culture.

Antituberculous therapy includes 2 months of therapy with four drugs, followed by 7 to 10 months of isoniazid and rifampin (for susceptible organisms) daily or twice weekly (see Chapter 134).[160] Surgical intervention is indicated in cases of spinal instability and neurologic impairment due to paravertebral abscess formation and for drainage of soft tissue abscesses. Nontuberculous *Mycobacterium* spp. infrequently cause osteomyelitis in immunocompromised individuals.

Anaerobic Bacterial Osteomyelitis

Anaerobic bacteria are associated with chronic and nonhematogenously acquired osteomyelitis.[161–163] Risk factors include surgery, trauma, diabetes mellitus, human bites, chronic otitis media or sinusitis, dental infection, fibrous dysplasia of bone, a prosthesis, and decubitus ulcers (Fig. 76.6). Children are more likely than adults to experience anaerobic osteomyelitis of the skull and facial bones.[161] Osteomyelitis of ribs follows contiguous spread from aspiration lung infection; *Actinomyces* spp. are the primary pathogens. Soft tissue swelling or abscess can be the presenting abnormality. Similarly, *Actinomyces* spp. can cause osteomyelitis of the maxilla or mandible, frequently without dental pathology.

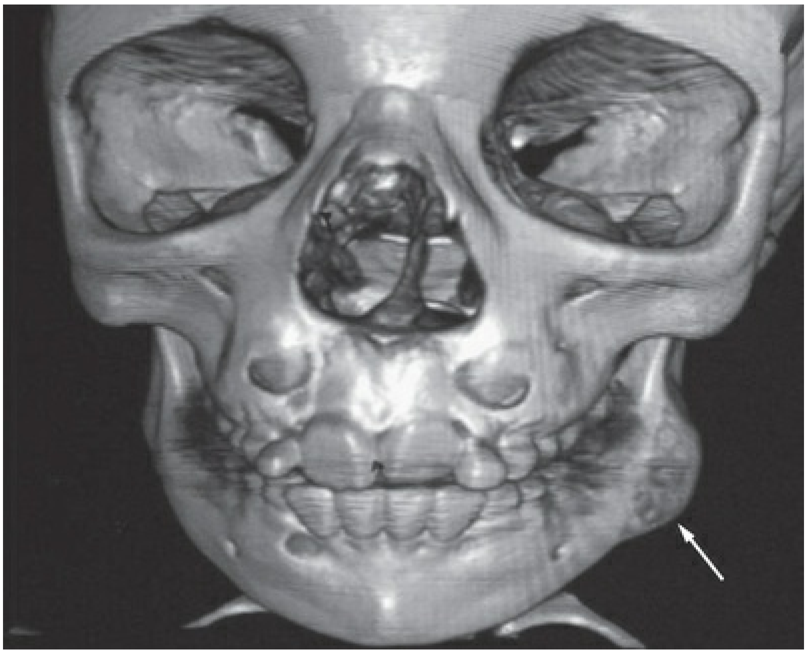

FIGURE 76.6 Actinomycosis of the mandible in a 9-year-old girl with history of painless expansion of the jaw over several months. Reconstructed spiral computed tomography shows expansion of bone with complex lytic and sclerotic mass *(arrow)*. Surgical biopsy confirmed *Actinomyces* osteomyelitis and fibrous dysplasia of bone. (Courtesy of L. Kaban and M. Pasternack, Massachusetts General Hospital, Boston, MA, and S.S. Long, St. Christopher's Hospital for Children, Philadelphia, PA.)

Infection usually is polymicrobial. Gram-positive cocci, *Bacteroides* spp., *Prevotella* spp., and *Fusobacterium* spp. are the most common anaerobes, and *S. aureus* is the most commonly associated aerobic isolate.[162]

Therapy consists of treatment of underlying conditions, surgical debridement of necrotic bone, and appropriate antibiotic therapy. Examples of effective antibiotics are clindamycin, metronidazole, imipenem, and amoxicillin-clavulanate. Many anaerobic isolates, including *Actinomyces*, are susceptible to penicillin. The choice of antibiotic depends on the specific organisms isolated and their potential for β-lactamase production. Therapy is protracted, frequently exceeding 1 year of oral penicillin or amoxicillin plus probenecid for actinomycosis.

Nonhematogenous Osteomyelitis

Contiguous Infection

Factors associated with the development of nonhematogenous osteomyelitis include open fractures requiring surgical reduction,[154,164] implanted orthopedic devices, decubitus ulcers, and neuropathic ulcers.[165,166] Facial osteomyelitis usually is caused by untreated mastoiditis, sinusitis, or periodontal abscess.[161,167] Osteomyelitis can occur after local soft tissue infection or direct inoculation of bone from human and animal bites.[168,169] Puncture wounds can lead to osteomyelitis of the foot (e.g., stepping on a nail or toothpick[170]) or the patella (e.g., kneeling on a needle).

Indolent presentation is common among children with nonhematogenous osteomyelitis. Fever occurs in less than one half of patients.[171] Persistent drainage or ulceration of the soft tissue over the affected bone is typical. A plain radiograph shows bony destruction. The peripheral white blood cell count often is normal, and ESR and CRP levels also can be normal.

Nonhematogenous osteomyelitis often is caused by *S. aureus,* although coinfection with gram-negative and anaerobic organisms occurs.[162] Examination of specimens from an associated sinus tract is unreliable in defining the cause of osteomyelitis.[172] Biopsy with culture of the affected bone is the best method of determining appropriate antibiotic therapy. Therapy should be prolonged if infection is chronic, sometimes with parenteral therapy followed by oral therapy for a total of 4 to 6 months.

The rate of recurrence of nonhematogenous osteomyelitis is as high as 40%, even with prolonged courses of antibiotic therapy.[171] Aggressive surgical debridement or other interventions are required in addition to antibiotic therapy. Implanted devices commonly must be removed for cure. Debridement followed by a muscle flap procedure to re-establish the blood supply in decubitus ulcer–associated osteomyelitis frequently is beneficial.[173]

Puncture Wound Osteochondritis of the Foot

Bacterial osteochondritis is a complication of puncture wounds of the foot, occurring in approximately 1.5% of these injuries.[174–176] Symptoms of osteochondritis, which appear several days to weeks after the initial injury, include increasing tenderness, erythema, and swelling at the site of the puncture.

Infection usually is caused by *Pseudomonas aeruginosa*,[177] often as a result of inoculation from the colonized moist soles of tennis shoes.[127] *S. aureus* is the usual pathogen if symptoms began within 3 to 5 days of injury. Obtaining specimens from bone for microbiologic diagnosis is desirable.

Empiric antibiotic therapy should cover *P. aeruginosa* and *S. aureus.* Ticarcillin-clavulanate, piperacillin-tazobactam, ceftazidime, or cefepime, with or without an aminoglycoside, is appropriate empiric therapy if MRSA is unlikely. Treatment with oral ciprofloxacin in conjunction with surgical debridement also is effective.[178] With appropriate surgical debridement, short-duration (7 to 10 days) antibiotic therapy has been effective for *P. aeruginosa*, as has 3 to 4 weeks of antibiotic therapy without debridement.[174–178]

Chronic Recurrent Multifocal Osteomyelitis

Chronic, recurrent, multifocal osteomyelitis (CRMO) is an inflammatory disease of children and young adults characterized by recurring episodes of low-grade fever, swelling, and pain over affected bones and with radiologic abnormalities suggesting osteomyelitis[179–181] Females are more frequently affected than males.[182] The median age of onset of illness is 10 years. CRMO sometimes is associated with palmoplantar pustulosis,[183] psoriasis, arthritis, sacroiliitis, inflammatory bowel disease,[184] and Sweet syndrome.

Radiographic abnormalities occur most commonly in the metaphysis of long bones (characterized by radiolucent bone lesions with reactive sclerosis) and show soft tissue swelling.[182,185,186] The sternal end of the clavicle, the vertebral bodies, and the smaller bones of the hands and feet often are involved. Radiographic changes are similar to those seen in acute osteomyelitis, but multiple, often symmetric lesions occur in CRMO. Bone scans and MRI are useful in determining the extent and evolution of disease.[185,187,188] An infectious cause of CRMO has not been determined; the condition may be an autoinflammatory condition.

The course of CRMO consists of prolonged bone pain with remissions and relapses over several years; the mean duration of disease is 6 years.[189] In a long-term follow-up study of 23 patients with CRMO, 26% had active disease at a median of 13 years after diagnosis.[184] Although the clinical outcome for most patients is good, approximately 20% of patients have a prolonged and severe course. Young age at onset and multiple sites of involvement predict a less favorable outcome.[190] Treatment with a variety of antibiotics has had no apparent effect on the course or outcome. Some experts have advocated the use of corticosteroids or nonsteroidal anti-inflammatory agents for relief of symptoms.[182,186] Other therapies have included colchicine, interferon γ, interferon α, and infliximab.[184,190,191]

Because multifocal bone lesions in childhood can occur with neuroblastoma, histiocytosis, leukemia, and staphylococcal osteomyelitis, histologic examination and culture of bone specimens should be performed. Histologic findings in CRMO cases show nonspecific acute and chronic inflammatory changes. In the chronic phase of the disease, granulomatous changes can be seen.[192]

Chronic Osteomyelitis

Chronic osteomyelitis develops in less than 5% of cases of AHO.[193] More often, it complicates nonhematogenous osteomyelitis.[171]

Chronic osteomyelitis is characterized by alternating periods of quiescence and recurrence of pain, swelling, and sinus tract drainage. It can persist for years despite prolonged antibiotic therapy. Infections often are polymicrobial, and with skeletal growth, the original metaphyseal infection moves to become a lytic lesion in the diaphysis.[163,173]

Surgical debridement of necrotic bone is the primary management. Alternative therapeutic approaches include the use of antibiotic-impregnated polymethyl methacrylate beads,[194,195] local antibiotic delivery by implantable pumps,[196] and suction vacuum devices or bone grafts, skin grafts, and muscle flaps to eliminate dead space and improve vascularity.[197]

Infectious and Inflammatory Arthritis

David K. Hong, Kathleen Gutierrez

Infectious arthritis in children can be caused by bacteria, viruses, or fungi. Pyogenic arthritis is characterized by a purulent inflammatory response, usually caused by a bacterial infection. Reactive (inflammatory) arthritis is inflammation of one or more joints that can result from a response to infection elsewhere in the body or from a systemic inflammatory or autoimmune disorder.

Infectious Arthritis

Pyogenic Arthritis

Epidemiology

The incidence of pyogenic (bacterial) arthritis is less than that of transient synovitis and varies substantially (i.e., 1 to 37 cases per 100,000 children) depending on the population studied.[1,2] Although pyogenic arthritis occurs in all age groups, the peak incidence of disease is in children younger than 3 years of age.[3–5]

A history of trauma temporally related to the onset of arthritis caused by *Staphylococcus aureus* is common.[6,7] Upper respiratory tract infection frequently precedes pyogenic arthritis caused by *Haemophilus influenzae* type b (Hib) and *Kingella kingae.*[6,8,9] Gastroenteritis and aphthous stomatitis also can precede arthritis caused by *K. kingae.*[10] Although most children have no underlying disorder, risk factors for pyogenic arthritis include immunodeficiency, hemoglobinopathy, diabetes, intravenous drug abuse, and rheumatoid arthritis.[11–13]

Pathophysiology

Most cases of pyogenic arthritis in childhood follow the hematogenous spread of organisms to the vascular synovium of the joint space.[14] Animal models of Hib bacterial arthritis illustrate possible mechanisms of articular damage.[15] Bacterial endotoxin in the joint space stimulates release of tumor necrosis factor and interleukin-1.[16,17] These cytokines stimulate production of proteinases by synovial cells and chondrocytes, enhancing leukocyte migration. Neutrophil elastases augment destruction of cartilage matrix in the joint.[16–19]

Bacteria can spread to joints from contiguous osteomyelitis.[20] The transphyseal blood vessels in the child younger than 18 months facilitates spread of infection from the metaphysis across the growth plate to the epiphysis and adjacent joint space.[21] The joint capsule of the hip and shoulder overlies the bony metaphysis of the femur and humerus, allowing direct extension of bone infection into these joint spaces. Primary pyogenic arthritis infrequently extends into the bone to cause a secondary osteomyelitis except from hip and shoulder joints, in the neonate, or associated with *Kingella* infection. Joints also can be infected from penetrating wounds, intra-articular injections of medications, arthroscopy, and prosthetic joint surgery.[22]

Etiology

Age is the most important predictor of the cause of pyogenic arthritis.[5,6,23–26] *S. aureus,* enteric gram-negative organisms, and group B *Streptococcus* (GBS) are the most frequent causes of pyogenic arthritis among neonates. Methicillin-susceptible *S. aureus* (MSSA), community-associated methicillin-resistant *S. aureus* (CA-MRSA), *K. kingae, Streptococcus pyogenes,* and *Streptococcus* *pneumoniae* cause pyogenic arthritis in children younger than 5 years of age. In one series, *K. kingae* was the most common cause of pyogenic arthritis in children younger than 36 months.[23] *K. kingae* is being reported with increasing frequency as a cause of pyogenic arthritis in the United States.[27–30] Hib infection has become rare among immunized immunocompetent children.[31–33]

Although *S. pneumoniae* caused approximately 6% of cases of pyogenic arthritis before universal pneumococcal conjugate vaccination,[34] cases of invasive disease due to vaccine serotypes have decreased dramatically.[35,36] *S. aureus* and *S. pyogenes* are the most common causes of pyogenic arthritis in children older than 5 years. CA-MRSA osteoarticular infections are common,[37] are more aggressive than MSSA infections involving multiple bones and joints[38] and sometimes are associated with venous thrombosis and pulmonary disease.[37,39]

Other organisms reported to cause pyogenic arthritis in children after *K. kingae*,[40] include *Salmonella* spp.,[41,42] β-hemolytic streptococci other than serogroups A or B,[43] and rarely, anaerobic bacteria.[44,45]

Joint infections caused by *Pseudomonas aeruginosa* and *Candida* spp. are reported for intravenous drug abusers.[12] *Brucella* spp. infection should be considered if a history of travel to endemic areas, contact with livestock, or consumption of unpasteurized dairy products is elicted.[46,47] Arthritis related to *Bartonella henselae* infection has been reported.[48]

Clinical Manifestations

Fever, malaise, poor appetite, and irritability are heralding systemic symptoms. Pain in the affected joint usually occurs early in the course of the illness. As infection progresses, the joint becomes swollen and the overlying skin red. Limp or refusal to walk occurs with infection of a lower extremity. If the affected joint is in the upper extremity, pseudoparalysis or refusal to use the affected joint is seen, and manipulation causes pain. The infected joint is swollen, red, warm, and tender on palpation. The range of joint motion is decreased.

The joints of the lower extremities, especially the knees, are the most common sites of pyogenic arthritis[5,8] (Table 77.1). More than 90% of cases of pyogenic arthritis are monoarticular.[5,25] However, multiple joints can be involved, particularly with infections caused by *Neisseria gonorrhoeae, N. meningitidis,* and *Salmonella* spp.

TABLE 77.1

Frequency of Joint Involvement in 1050 Children With Pyogenic Arthritis

Anatomic Site	No. of Patients	Percentage (%) of Patients
Knee	467	41
Hip	287	25
Ankle	143	13
Elbow	116	10
Shoulder	53	5
Other[a]	70	6
Total[b]	1136	100

[a] Includes the sacroiliac joint, joints of hands and feet, and the sternoclavicular joint.

[b] Some children had more than one joint affected.

Data from references 4, 5, 7, 8, 96, and 98.

The diagnosis of pyogenic arthritis of the hip can be difficult because there is often no obvious joint swelling, and signs and symptoms are nonspecific, especially in infants and young children. Infants with pyogenic arthritis of the hip are irritable when the hip is moved (e.g., during diaper changes). Soft tissue swelling around the hip joint occasionally occurs and can extend to involve the entire leg.[49] The affected hip often is held in a flexed, externally rotated and abducted position.[50] Older children with pyogenic arthritis of the hip limp or refuse to walk and complain of pain, which sometimes is referred to the knee.[51] Range of motion of the hip joint is decreased markedly.

Diagnosis

The erythrocyte sedimentation rate (ESR) is more than 20 mm/hr (mean, 44 to 65 mm/hr) for most patients with pyogenic arthritis.[52,53] Similarly, the level of C-reactive protein (CRP) often is increased (mean, 8.5 mg/dL).[53,54] A normal CRP level is a good negative predictor for pyogenic arthritis. In one study, the probability that the patient did not have pyogenic arthritis was 87% if the CRP was less than 1.0 mg/dL.[55]

Excellent sensitivity for the diagnosis of osteoarticular infections is obtained by using both the ESR and CRP.[54] However, children with pyogenic arthritis caused by *K. kingae* can lack fever or elevation of inflammatory markers, or both.[56]

Analysis of joint fluid helps to differentiate bacterial from other causes of arthritis (Table 77.2). Joint fluid in bacterial arthritis typically has a cloudy appearance. A leukocyte count of >50,000 cells/mm^3 with a predominance of neutrophils strongly suggests bacterial infection, even if the culture result for the joint fluid is negative.[57,58] However, synovial fluid white blood cell (WBC) counts of <50,000/mm^3 can occur in cases of bacterial arthritis, particularly when infection is caused by *K. kingae*.[10,25,40,50,56] Fluid WBC counts of >50,000/mm^3 with neutrophil predominance can occur in children with juvenile idiopathic arthritis or Lyme disease.[59,60] Synovial fluid glucose and protein levels do not differentiate reliably among most infectious and inflammatory processes and therefore have limited value.[61]

TABLE 77.2

Characteristic Synovial Fluid Findings

Diagnosis	WBCs/mm^3 (Typical)	WBCs/mm^3 (Range)	% PMNs (Typical)
Normal	<150	—	<25
Bacterial arthritis	>50,000	2000–300,000	>90
Tuberculous arthritis	10,000–20,000	40–136,000	>50 (range, 10–99)
Lyme arthritis	40,000–80,000	180–140,000	>75
Candidal arthritis	—	7500–150,000	>90
Viral arthritis	15,000	3000–50,000	<50 (variable)
Reiter syndrome	15,000	10,000–22,000	>70 (range, 37–98)
Rheumatoid arthritis	—	2000–50,000	>70
Rheumatic fever	25,000	2000–50,000	>70

PMNs, polymorphonuclear cells; WBCs, white blood cells.

Data from references 57, 59, 60, 144, 148, and 176.

Blood culture should be obtained and synovial fluid sent for Gram stain, culture, and WBC count. Isolation of *K. kingae* is enhanced when synovial fluid is inoculated directly into fluid blood culture medium.[28] Use of real-time polymerase chain reaction (rt-PCR) testing increases the identification of *K. kingae* in culture-negative joint fluid.[62] Similarly, serologic testing and occasional detection of *Borrelia burgdorferi* by PCR in joint fluid aid diagnosis of Lyme arthritis.[63]

For adolescents, specimens should be obtained from the cervix or urethra, throat, skin lesions, and rectum for isolation of *N. gonorrhoeae.* Alternatively, nucleic acid testing of urine is performed.

When appropriate cultures are obtained, the bacterial cause is confirmed in 60% to 70% of cases of pyogenic arthritis.[5,25] Blood cultures are positive in 40%[4,22] of cases, and joint fluid culture is positive in 50% to 60%.[4,5,8,25]

Imaging Studies

Children with suspected pyogenic arthritis should have plain radiographic studies to exclude osteomyelitis or other osseous abnormalities. Soft tissue swelling and widening of the joint can be observed in children with pyogenic arthritis. Erosion of subchondral bone may be evident 2 to 4 weeks after onset of infection.[64]

Swelling of the hip capsule and lateral displacement or obliteration of the gluteal fat planes are early radiographic findings for pyogenic arthritis of the hip.[64] With continued swelling of the hip capsule, the femoral head is displaced upward and outward, and lateral subluxation can occur. Concomitant osteomyelitis of the femur may occur.[50] These findings are particularly common in infants, although in this age group, radiographic findings are difficult to interpret because of minimal ossification of the proximal femur. A plain radiograph sometimes is normal for children with proven pyogenic arthritis of the hip.[65]

Ultrasonography (US) should be performed in suspected pyogenic arthritis of the hip. If fluid is detected in the joint, a diagnostic aspiration should be performed under US guidance.[66,67] False-negative US results reported for children subsequently diagnosed with pyogenic arthritis are related to inadequate imaging or imaging performed very early (<24 hours) after the onset of symptoms.[68]

Although technetium phosphate radionuclide scanning typically is not used in the diagnosis of pyogenic arthritis, a scan can be valuable in evaluating involvement of deep joints such as the hip or sacroiliac joint. A characteristic finding is increased activity in the early (blood pool) phase and increased bony uptake on both sides of the joint (which is uncharacteristic in osteomyelitis). Similarly, computed tomography (CT) may be helpful in the diagnosis of arthritis in areas of complex anatomy, such as the shoulder, hip, and sacroiliac joint.

Magnetic resonance imaging (MRI) is highly sensitive for the early detection of inflamed or infected joints.[69] Abnormal MRI findings in pyogenic arthritis include periarticular high-intensity signal and periarticular abscesses in some cases.[70] MRI can delineate abnormalities of adjacent bone and soft tissue and the extent of cartilage destruction. Compared with patients with transient synovitis, those with pyogenic arthritis are more likely to have MRI findings of high-intensity signals in the bone marrow[71] and decreased signal in the femoral epiphysis on fat-suppressed, gadolinium-enhanced, T1-weighted images.[72]

Treatment

Children with pyogenic arthritis should be managed in conjunction with an orthopedic surgeon experienced in treating children. Goals of therapy include decompression, sterilization of the joint space, and removal of inflammatory debris.

All children with pyogenic arthritis of the hip require prompt surgical drainage and irrigation of the joint space.[73–75] Delay in drainage increases the likelihood of permanent damage because increased intra-articular pressure can compromise blood supply, resulting in avascular necrosis of the femoral head. Muscle spasms also can occur, predisposing the patient to dislocation. Open surgical drainage of joints other than the hip usually is not required. However, aspiration must be performed promptly to decompress the joint and obtain synovial fluid for analysis. Repeated aspirations often are necessary when fluid reaccumulates. Concurrent osteomyelitis can be associated with the need for repeated debridement of the joint.[76] Debridement by arthroscopy has been undertaken in some cases of pyogenic arthritis of the knee and hip.[77,78]

The initial choice of antibiotics is based on age, clinical history, and physical examination of the patient. Adequate penetration into the joint is essential. Penicillin, ampicillin, nafcillin, methicillin, dicloxacillin, some first- and third-generation cephalosporins, clindamycin, vancomycin, and aminoglycosides attain acceptable concentrations in joints after intravenous or intramuscular administration. Agents that are well absorbed from the gastrointestinal tract attain adequate joint space concentrations after oral administration.[24,79–83] Because antibiotics achieve high synovial fluid-to-serum ratios, there is no role for intra-articular instillation of antibiotics, which can produce chemical irritation and inflammation.

Parenterally administered therapy is used initially (Table 77.3). Antistaphylococcal therapy should be given for a child of any age. Infants younger than 3 months of age should be treated with antibiotics active against *S. aureus*, gram-negative enteric organisms, and GBS. Children 3 months to 5 years of age should receive empiric therapy for *S. aureus, K. kingae, S. pneumoniae,* and *S. pyogenes.* Although Hib infection is uncommon in immunized children, other serotypes of *Haemophilus* occasionally cause pyogenic arthritis.[84] Children older than 5 years are treated for the most likely pathogens, *S. aureus* and streptococci. Empiric therapy for *N. gonorrhoeae* is indicated for the sexually active adolescent.[85]

TABLE 77.3

Empiric Antibiotic Therapy for Pyogenic Arthritis in Children

Age	Likely Pathogens	Antibiotic	Dosage[g]	
			mg/kg per day	Divided Doses/Day
Neonate (doses are for infants >2000 g and >7 days old with normal serum creatinine levels)	*Staphylococcus aureus*[a] Group B *Streptococcus* Gram-negative bacilli	Nafcillin	100	4
		or		
		Vancomycin	30	2
		or		
		Clindamycin	20	4
		plus		
		Cefotaxime	150	3
		or		
		Gentamicin	4	1
Child ≤5 yr	*S. aureus*[a] *Haemophilus influenzae*[b] *Kingella kingae*[c] *Streptococcus pyogenes* *Streptococcus pneumoniae*	Nafcillin	150	4
		or		
		Vancomycin	45–60	3
		or		
		Clindamycin[d]	30–40	3
		plus		
		Cefotaxime	150	3
		or		
		Cefuroxime	150	3
		or		
Child >5 yr	*S. aureus*[a] *Streptococcus pyogenes*	Nafcillin	150	4
		or		
		Vancomycin	45–60	3
		or		
		Clindamycin[d]	30–40	3
Adolescent (sexually active)	*Neisseria*	Ceftriaxone[e,f]	50	1

	gonorrhoeae (consider)			

[a] If more than 10% of community-acquired isolates are methicillin-resistant *Staphylococcus aureus*, consider empiric therapy with vancomycin or clindamycin until culture and susceptibility results are available. If infection is confirmed to be caused by MRSA, see Clinical Practice Guidelines by the Infectious Diseases Society of America for treatment of MRSA infections in adults and children for specific dosing recommendations.[87]

[b] Children who have been completely immunized are less likely to have *Haemophilus influenzae* type b infection.

[c] If empiric therapy with vancomycin or clindamycin is used, consider adding ampicillin-sulbactam, a second- or third-generation cephalosporin for *Kingella kingae* coverage in patients younger than 36 months of age.

[d] Maximum oral dose of clindamycin is 1.8 g/day; the adult dose is 600 mg/dose PO or IV given every 8 hours.

[e] The maximum dose of ceftriaxone 1 g/day, given in a single dose.

[f] The addition of azithromycin (1 g) is recommended for adults with gonococcal arthritis. No data exist for children.

[g] Not to exceed adult dosing.

Empiric therapy with vancomycin or clindamycin is indicated when CA-MRSA isolates exceed 10%.[86] Resistance to clindamycin may preclude its use as empiric therapy in many communities. Most *S. pyogenes* and *S. pneumoniae* isolates are susceptible to vancomycin and clindamycin, although susceptibility testing should be performed for both organisms. Neither drug is effective in treating infection caused by *K. kingae.* Most β-lactam antibiotics, including ampicillin, ampicillin-sulbactam, and second- and third-generation cephalosporins, have activity against *K. kingae.*[26]

Nafcillin, oxacillin, and a first-generation cephalosporin remain the drugs of choice if MSSA is isolated. Choices of antibiotics for MRSA infections in children are limited. Vancomycin is effective, but no absorbable oral formulation exists. If MRSA is susceptible to clindamycin (including no inducible resistance), clindamycin is an excellent choice as an oral agent. Linezolid and daptomycin have been used in some patients with serious MRSA infection, although data regarding daptomycin use in children are limited. Linezolid has excellent oral bioavailability, but thrombocytopenia, anemia, and leukopenia can occur after 2 or 3 weeks; and lactic acidosis has been reported. Longer-term use is associated with peripheral and optic neuropathy. Linezolid is a weak, reversible monoamine oxidase inhibitor, and serotonin syndrome has occurred in children who also are receiving a serotonin-receptor inhibitor. The Infectious Diseases Society of America has published guidelines for the management of MRSA infections.[87]

Specific therapy based on culture results and susceptibility testing is continued parenterally until the child is afebrile; joint pain, swelling, and erythema have decreased; and joint mobility has increased. Markers of the acute phase response should decrease. Because the CRP level normalizes more quickly when infection is controlled than the ESR (which typically is elevated for up to 2 weeks), CRP is used to monitor the early response to therapy.[54] Open drainage of any joint (with lysis and irrigation of loculated collections) should be undertaken when aspirations yield samples that are persistently positive on culture.

Orally administered antibiotic therapy can be substituted for parenteral treatment after adequate control of infection and inflammation has been achieved if an oral antibiotic with appropriate coverage is available and if adherence and careful monitoring can be ensured[83,88–91] (Table 77.4). Use of clinical practice guidelines have been successful in decreasing the number of days of parenteral antibiotics and duration of hospitalization without increasing complications or sequelae.[92]

TABLE 77.4

Oral Antibiotic Therapy for Pyogenic Arthritis[a]

Agent	Dosage[b]	
	mg/kg per day	Divided Doses/Day
Dicloxacillin	75–100	4
Cephalexin	100	3–4
Clindamycin	30–40	3

[a] Doses can be modified depending on results of serum bactericidal levels. The oral dose of β-lactam antibiotics used for osteoarticular infections is two to three times the usual dose.

[b] Not to exceed adult dosing.

For children in whom oral therapy is not feasible, outpatient parenteral antibiotic therapy administered through a tunneled central venous catheter or a peripherally inserted central catheter has been successful. Catheter-related mechanical and infectious complications can occur with prolonged intravenous administration of antibiotics, and the risk versus benefit of prolonged central venous access should be considered carefully.[93]

Duration of antimicrobial therapy remains a subject of considerable debate. Duration usually is determined by the specific pathogen, clinical and laboratory response, and whether adjacent osteomyelitis exists. Joint infections caused by *S. aureus* and gram-negative enteric organisms usually are treated for at least 3 to 4 weeks. Arthritis caused by *H. influenzae, S. pneumoniae, S. pyogenes,* and *K. kingae* is treated for 2 to 3 weeks, depending on the clinical response. Therapy for less than 2 weeks for children in Finland with culture-positive arthritis was successful in most cases.[90] None of the children in this study had MRSA infection, and several children with hip infections required longer courses of treatment. A larger, controlled, prospective study is necessary to better evaluate the adequacy of short-course antibiotic therapy.[94]

Prognosis

Sequelae of pyogenic arthritis in children include abnormalities of bone growth, limitation of joint mobility, unstable articulation, and chronic dislocation of the joint. Joint dysfunction may not become apparent for months to years after infection.[95] An estimated 10% to 25% of children with pyogenic arthritis have residual dysfunction.[5,95]

Several risk factors for the development of sequelae have been identified, including age younger than 6 months[3–8]; infection of the adjacent bone, which is evident in 10% to 16% of children with pyogenic arthritis and increases the likelihood of sequelae to approximately 50%[5,39,74,96,97]; infection of the hip or shoulder[5,95,98]; a delay of 4 days or more before decompression and antibiotic therapy[13,50,99–101]; and prolonged time to sterilization of synovial fluid.[102] Staphylococcal and gram-negative bacillary infections carry a high risk of sequelae, whereas meningococcal and gonococcal infections carry a low risk.

Special Situations and Pathogens

Neonatal Arthritis

Risk factors for pyogenic arthritis in the neonate include umbilical vessel catheterization, insertion of a central venous catheter,[103] femoral vessel blood sampling,[49,104,105] and possibly fetal breech presentation.[106] Pyogenic arthritis often is a complication of osteomyelitis, and the onset may be insidious (see Chapter 92). The hip and knee are the most frequently involved joints.[104]

S. aureus, N. gonorrhoeae, and *Candida* spp. frequently cause polyarticular infection. If infection is contracted in the hospital, MRSA and MSSA, enteric gram-negative organisms, and *Candida* spp. are common causes. GBS, *S. aureus,* and *N. gonorrhoeae* are the pathogens most commonly isolated from neonates who develop joint infections after hospital discharge.[107]

Gonococcal Arthritis

Arthritis caused by *N. gonorrhoeae* must be considered in sexually active adolescents.[85] The incidence of disseminated gonococcal infection in people with urethritis or cervicitis is approximately 1%.[108] Disseminated gonococcal infection is characterized by mild fever, polyarthralgia, rash, tenosynovitis, and suppurative arthritis, and it is more common in girls, often during menstruation. Suppurative arthritis most often involves the knee. The hand, wrist, ankle, elbow, and foot are involved less often, and infection of the shoulder or hip is uncommon.[109] Skin lesions occur in approximately 40% of patients. Lesions typically are few in number and represent vasculitis. Lesions occur most frequently on extremities or over affected joints, are papular with a hemorrhagic component, and evolve into vesiculopustular lesions on an erythematous base.[110] Other skin lesions, including bullae and purpura, have been described.[13]

Culture of joint fluid is positive in only 25% to 35% of cases. Cultures of skin lesions and blood, cervical, urethral, rectal, vaginal, or throat specimens may be positive when culture of the joint fluid is negative. Cultures obtained from normally sterile sites should be inoculated onto chocolate agar. Cultures from nonsterile sites should be inoculated immediately onto Thayer-Martin agar and incubated in carbon dioxide. *N. gonorrhoeae* also can be detected by PCR or other DNA amplification tests on first-voided urine specimens and urethral and cervicovaginal swab samples.

Because of the increasing prevalence of penicillin-resistant *N. gonorrhoeae,* 7 days of treatment with a parenterally administered third-generation cephalosporin, such as ceftriaxone or cefotaxime, is recommended.[108,109,111] The addition of azithromycin is recommended for adults with gonococcal arthritis, but there are no data on dual therapy for children.[111] Marked improvement in fever and joint pain usually occurs 1 to 2 days after beginning therapy. Sequelae are rare.

Polyarthritis, Fever, and Rash

Bacterial causes of the clinical syndrome of fever, polyarthritis, and rash include infection with *N. meningitidis* and *N. gonorrhoeae,* rat-bite fever (i.e., *Streptobacillus moniliformis* or *Spirillum minus),* bacterial endocarditis, and rheumatic fever[112]; multiple viruses also are considered (discussed later). Noninfectious causes include Kawasaki disease, serum sickness, erythema multiforme, and other autoinflammatory and autoimmune diseases.

Lyme Arthritis

Arthralgia occurs early in the course of Lyme disease and is recurrent in 18% of individuals. Approximately one half of patients with Lyme disease have arthritis,[113] with a typical onset 1 to 2 months after erythema migrans with sudden onset of monoarticular or oligoarticular joint pain. Joints involved, in descending order of frequency, include the knee, shoulder, elbow, temporomandibular joint, ankle, and wrist. Involvement of the hip or small joints is unusual.[60] In a Lyme endemic area, however, 5.2% of children evaluated in an emergency department because of acute hip pain who had serology performed had Lyme arthritis; symptoms and test results frequently were similar to transient synovitis.[114]

Patients characteristically are not ill, although about half have fever. Affected joints are warm and swollen and have large effusions, but motion typically is not severely limited. The peripheral white blood cell count often is normal, but the ESR and CRP levels usually are modestly elevated.[115] Synovial fluid leukocyte counts range from 180 to 140,000 cells/mm^3, and polymorphonuclear cells predominate.[60] *B. burgdorferi* DNA has been detected by PCR of synovial fluid of patients with Lyme arthritis. Testing of serum for antibodies usually can confirm the diagnosis.[63] Patients with Lyme arthritis are more likely to have MRI findings of myositis, lymphadenopathy, and lack of subcutaneous edema compared with children with pyogenic arthritis.[116]

Lyme arthritis is treated with amoxicillin or doxycycline, depending on age (see Chapter 185). Duration of therapy usually is 4 weeks. Children with multiple recurrences or persistent arthritis sometimes require intravenous or intramuscular ceftriaxone or intravenous penicillin for 14 to 28 days. The prognosis for children is excellent.[117] Rupture of fluid from knee joint into the popliteal space (e.g., popliteal cyst, Baker cyst) with a brisk local inflammatory response has been described.[118]

If untreated, recurrences of arthritis are common. They usually are separated by months to years. Frequency and duration of attacks decrease over time. Chronic synovitis develops in approximately 11% of untreated individuals.

Viral Arthritis

Arthritis as a result of viral infection can occur by direct viral invasion of the synovium or through immune complex deposition (Box 77.1). The viruses most commonly associated with the development of arthritis include rubella, parvovirus B19, certain arboviruses (e.g., chikungunya), and hepatitis B.

Box 77.1

Viruses That Cause Arthritis

Togaviridae

Rubella virus

Chikungunya virus

Ross River virus

O'nyong-nyong virus

Mayaro virus

Sindbis virus

Barmah Forest virus

Parvoviridae

Parvovirus B19

Paramyxoviridae

Mumps virus

Picornaviridae

Echovirus

Coxsackievirus B

Retroviridae

Human immunodeficiency virus type 1

Human T-lymphotropic virus type 1

Herpesviridae

Herpes simplex virus 1

Varicella-zoster virus

Cytomegalovirus

Epstein-Barr virus

Flaviviridae

Hepatitis C virus

Hepadnaviridae

Hepatitis B virus

Rubella Virus

Arthritis after rubella infection is uncommon in childhood, but it occurs in 30% of women and 15% of men. Arthritis usually develops 1 to 2 days after the onset of rash, although arthritis has preceded the rash in a few cases. Symmetric involvement of small joints of the hands is most common. Wrists and knees are sometimes affected.

Analysis of joint fluid shows a predominance of mononuclear cells. Rubella virus has been isolated from synovial fluid. Symptoms resolve after several days, and long-term sequelae do not occur. Arthralgia and arthritis occur in approximately 25% of postpubertal females who receive live attenuated rubella vaccine. Joint symptoms begin 7 to 21 days after vaccination and usually are mild and self-limited.[119,120]

Parvovirus

Symptoms of arthritis or arthralgia were reported by 80% of adults and 8% of children during an outbreak of erythema infectiosum,[121] and arthritis can occur in the absence of rash. Infection often is symmetric and polyarticular, and the joints of the hands, wrists, and knees are involved most commonly. Children are more likely to have asymmetric involvement of a few joints.

Levels of total hemolytic complement are low in some people with parvovirus B19 arthritis, suggesting an immune complex–mediated pathogenesis. Arthritis associated with parvovirus B19 infection usually is self-limited. Resolution of symptoms occurs within 1 to 2 months.

Hepatitis Viruses

Arthralgia can occur as a prodromal symptom of infection with hepatitis A or B viruses, but arthritis occurs only with hepatitis B infection.[122,123] Joint symptoms precede the onset of icterus by 1 or 2 weeks. Multiple small joints of the hands usually are involved. Asymmetric involvement of the knees, elbows, ankles, and shoulders sometimes is seen.

An urticarial or maculopapular rash, usually involving the lower extremities, appears simultaneously with the joint findings in 30% to 40% of patients with arthritis. Hepatitis C viral infection has been associated with development of polyarthralgia and polyarthritis in a few patients.[124]

Arboviruses

Several arboviruses in the family Togaviridae, genus alphavirus, found in Australia, Africa, Asia, and South America cause systemic illness in which arthritis is a predominant manifestation. All are transmitted by bites of mosquitoes or ticks.

Chikungunya virus infection is endemic in Africa, India, and Southeast Asia and recently has expanded into the Western Hemisphere, primarily in the Caribbean and Central and South America.[125] Illness is biphasic, heralded by abrupt onset of fever, nausea, vomiting, and intense pain in one or more joints. The first phase of illness lasts 1 to 6 days, the patient becomes afebrile for 3 days, and then fever recurs. The second phase of illness is characterized by pharyngitis, rash, lymphadenopathy, and persistent arthritis. Children sometimes have febrile seizures and severe hemorrhagic manifestations.

Epidemic polyarthritis caused by Ross River virus occurs most frequently in Australia.[126] Clinical manifestations include fever, papular, petechial or morbilliform rash, adenopathy, and polyarthritis. Small joints of the hands and feet are affected most commonly. Most patients recover spontaneously within 2 weeks. Barmah Forest virus, also endemic to Australia, causes fever, polyarthritis, and rash.[127]

O'nyong-nyong virus (East Africa), Sindbis virus (Africa, Australia, Asia, Europe, and the Middle East), and Mayaro virus (Central and South America) infections cause febrile illnesses that are characterized by rash, adenopathy, arthralgia, and arthritis.

Other Viruses

Other viruses less commonly associated with arthralgia or arthritis include Epstein-Barr virus,[128] enteroviruses (i.e., echovirus and coxsackievirus B),[129] mumps virus,[130] varicella-zoster virus,[131] cytomegalovirus, and herpes simplex virus.[132]

Persistent or intermittent arthralgia involving the knee or shoulder has been reported in 35% to 45% of adults with human immunodeficiency virus (HIV) infection[133,134] but in only 15% of children with this infection.[135]

Mycoplasma Species

Mycoplasma pneumoniae, M. hominis, M. salivarium, and *Ureaplasma urealyticum* have been identified in joint fluid of patients with arthritis.[136–141] Most patients are immunocompromised or have suffered trauma to the joint. Characteristically, onset is insidious, with minimal systemic signs and a mildly affected, boggy joint with relative preservation of movement.

Mycobacterium Species

Skeletal tuberculosis occurs in 1% to 6% of tuberculosis cases. Isolated tuberculosis of the joint is uncommon.[142] Articular infection can represent reactivated or primary infection. The knees and hips are affected most commonly, but infection of other joints can occur. Chronic swelling or pain of the affected joint without systemic symptoms is common.

The tuberculin skin test (TST) is expected to be positive.[143] The synovial fluid WBC count typically ranges between 10,000 and 20,000 cells/mm^3, and neutrophils predominate. Synovial fluid cultures are positive in 79% of cases, and synovial biopsy is diagnostic in more than 90%.[144] MRI shows joint effusion with a high-intensity signal on T2-weighted images and postcontrast enhancement on T1-weighted images. Hypointense internal debris, synovial thickening, and cartilage destruction also may be seen.[145]

Nontuberculous mycobacteria can cause osteoarticular infections in immunocompromised hosts.[146,147]

Fungi

Fungal arthritis is unusual in healthy children, except in areas endemic for specific fungi. Chronic monoarticular arthritis is typical of most fungal joint infections. The diagnosis of arthritis usually requires microscopic evaluation of synovial biopsy specimens and culture of synovial tissue and fluid.

Candida species

Arthritis caused by *Candida* spp. occurs by hematogenous spread or rarely by direct inoculation of the organism into the joint space.[148] Risk factors in neonates include prematurity, use of broad-spectrum antibiotics, intravenous alimentation, and insertion of an intravascular catheter.[103,107] Risk factors in older children include immunosuppression and intravenous drug use.

Clinical manifestations vary. Children with disseminated disease have an acute onset of fever, systemic illness, and joint symptoms. In other cases, systemic symptoms are mild or absent. Joint symptoms may persist for months to years before a diagnosis is established. Neonates often have polyarticular involvement, but monoarticular infection is typical in older children. The knee is most frequently affected. Arthritis caused by *Candida* spp. in intravenous drug users often occurs in fibrocartilaginous joints, such as the sacroiliac joint, costochondral joints, and intervertebral disks.[149]

Synovial fluid WBC counts range from 7500 to 150,000 WBCs/mm^3, with neutrophil predominance. Diagnosis of fungal arthritis is confirmed by culture of synovial fluid or tissue. Culture of blood, urine, or cerebrospinal fluid may be positive in cases of systemic disease and especially in neonates.[148]

Fluconazole for 6 weeks or an echinocandin for 2 weeks followed by fluconazole for 4 weeks is the recommended treatment for *Candida* arthritis.[151] *Candida* spp. should be tested for susceptibility to fluconazole if this drug is considered. Adequate debridement of the joint is necessary for successful therapy.

Sporothrix schenckii

Sporothrix schenckii is a dimorphic fungus found worldwide in soil and decayed plant material. Individuals at risk for infection include those whose occupations place them in frequent contact with plant debris and moist soil. Infection in children is rare.

S. schenckii causes cutaneous and extracutaneous infection. Osteoarticular sporotrichosis is the most common manifestation of extracutaneous infection.[152] Joints most frequently involved include the knee, ankle, wrist, and elbows. Itraconazole is the treatment of choice, with amphotericin B recommended as alternative therapy.[153]

Aspergillus species

Aspergillus infection of the joint is uncommon and usually results from extension of infection from an adjacent bone. Children at risk include those with chronic granulomatous disease, chronic neutropenia, underlying cancer, and prolonged immunosuppression.[154]

Coccidioides immitis

Coccidioides immitis is found in soil in the southwestern United States and northern Mexico. Infection usually is asymptomatic or associated with localized pulmonary disease. Extrapulmonary manifestations include cutaneous lesions, lymphadenopathy, central nervous system infection, and osteoarticular infection. Joint involvement usually is unifocal and often adjacent to sites of osteomyelitis.[155]

Cryptococcus neoformans

Cryptococcus neoformans is found in soil contaminated by bird droppings. Infection typically involves the lungs, skin, or the central nervous system. Although bone lesions are found in 5% to 10% of cases, joint involvement is rare and usually results from infection in an adjacent bone.[156]

Histoplasma capsulatum

Histoplasma capsulatum is endemic to the central and southeastern United States, where large quantities of fungus are found in soil contaminated by bat or bird droppings. Infection usually is asymptomatic. Symptomatic infection is characterized by fever, chills, headache, cough, and chest pain. Approximately 10% of symptomatic patients have arthritis or severe arthralgia accompanied by erythema nodosum. Arthritis and arthralgia can be prolonged.

Antifungal therapy is not always indicated for the immunocompetent host (see Chapter 250).[157,158] Nonsteroidal anti-inflammatory drugs are recommended for relief of joint pain.[158]

Blastomyces dermatitidis

Blastomyces dermatitidis is found commonly in warm, moist soil containing decayed vegetation east of the Mississippi River.

Blastomycosis typically involves the lungs, skin, and genitourinary system. Skeletal disease occurs in 10% to 15% of cases.[159] Arthritis usually results from extension of osteomyelitis from an adjacent bone and usually is monoarticular but can be oligoarticular.[160]

Fungi are identifiable on a wet preparation of synovial fluid.[161] Itraconazole or other imidazoles have been used to treat blastomycoses.[162] Other fungal organisms, such as *Scedosporium* spp., are rare causes of arthritis.[163]

Reactive Arthritis

Reactive arthritis is inflammation in one or more joints related to an infection at a site distant from the joint.[164] Infections of the gastrointestinal, genitourinary, and respiratory tract are associated with reactive arthritis and an increasing number of pathogens are implicated.[165–170] Children are less likely than adults to develop reactive arthritis after enteric infection. Organisms most commonly associated with reactive arthritis are listed in Box 77.2.[164–167,169,171,172] Immune complex–associated arthritis occurs in 2% to 16% of cases of meningococcal disease.[173]

Box 77.2

Bacteria Associated With Reactive Arthritis

Gastrointestinal Pathogens

Shigella spp.

Salmonella spp.

Yersinia enterocolitica

Campylobacter spp.

Clostridium difficile

Sexually Transmitted Pathogens

Chlamydia trachomatis

Pyogenic and Reactive Arthritis–Causing Organisms

Streptococcus pyogenes

Neisseria gonorrhoeae

Neisseria meningitidis

A genetic susceptibility exists for development of reactive arthritis due to distant infection. Individuals who are HLA-B27 antigen positive have an increased incidence of disease.[174] About 80% of people with reactive arthritis associated with Reiter syndrome have the HLA-B27 gene. Reiter syndrome consists of arthritis, urethritis, and bilateral conjunctivitis. In children, symptoms usually follow a diarrheal illness.[175] In adults, Reiter syndrome also can follow an episode of nongonococcal urethritis. Although Reiter syndrome and reactive arthritis are sometimes used interchangeably, reactive arthritis is diagnosed in many children who do not have the triad of symptoms.

Reactive arthritis usually is polyarticular and involves the large joints of the lower extremities. Small joints, wrists, and elbows are involved less frequently. Sacroiliitis is more common among adults than children. Urethritis manifests with dysuria and pyuria. Mucous membrane ulcers in the mouth, rectum, or vagina or on the glans penis sometimes occur. Abnormalities of the eye include keratitis, uveitis, and corneal ulcerations.

The WBC count and ESR usually are elevated. The synovial fluid WBC count is less than 50,000 cells/mm^3 and has a predominance of neutrophils.[176] The ESR ranges from 20 to more than 100 mm/hr. Responsible pathogens are sometimes identified in stool or urethral specimens.

Nonsteroidal anti-inflammatory agents are useful in controlling symptoms. Antibiotic treatment of the predisposing bacterial organism may be appropriate when cultures are positive at the time of onset of joint symptoms.[173,177] In children, joint symptoms persist for 1 to 12 months, and recurrences are rare. The long-term prognosis of the disease is unknown.

Some bacteria cause direct infection of the joint and reactive arthritis. For example, *S. pyogenes* causes infective pyogenic arthritis and is associated with postinfectious reactive arthritis and rheumatic fever.[178] Poststreptococcal reactive arthritis typically occurs 3 to 14 days after streptococcal infection. Arthritis usually is symmetric, can involve large and small joints, and is nonmigratory, characteristics that differentiate it from the arthritis of acute rheumatic fever.[179] Similarly, *N. meningitidis, N. gonorrhoeae,* and *Salmonella* spp. sometimes are isolated from synovial fluid, but in other cases, infection at another site is associated with reactive arthritis.

Reactive arthritis also can be associated with a more generalized autoinflammatory or immunologic disorder, such as Crohn disease, ulcerative colitis, rheumatoid and rheumatic disorders, Kawasaki disease, hereditary autoinflammatory disorders, serum sickness, or Henoch-Schönlein purpura.

Diskitis

David K. Hong, Kathleen Gutierrez

Diskitis is an inflammatory process involving the intervertebral disks and the end plates of the vertebral bodies. It is associated with characteristic clinical and radiologic findings, but information about diskitis is derived primarily from case reports and retrospective studies of small numbers of patients.

Diskitis has been reported under a variety of other names, including spondylodiskitis, pyogenic infectious spondylitis, spondylarthritis, acute osteitis of the spine, intervertebral disk space infection, and benign osteomyelitis of the spine.[1–6] The definition of diskitis varies among studies, and it is often difficult to differentiate disk space inflammation alone from vertebral osteomyelitis. Disk space inflammation likely is part of a spectrum of disease that includes vertebral osteomyelitis, but diskitis appears to have a more benign clinical course.[7,8]

There has been no consistent approach to the diagnosis, treatment, and long-term follow-up of patients with diskitis. Knowledge about the incidence, causes, and optimal treatment of this infection therefore remains limited.

Epidemiology and Etiology

Although the incidence of diskitis is unknown, it appears to be uncommon. In one center, diskitis occurred at a rate of approximately 1 or 2 cases per 30,000 clinic visits per year.[1] Most cases occur among children 6 years of age or younger,[1,9–13] although cases have been reported for older children and adolescents. Disk space infection in adults most commonly occurs in the postoperative setting. Spontaneous diskitis is uncommon in adults,[14,15] but when reported, it has been associated with older age, diabetes mellitus, and systemic infection.[16]

Diskitis is probably the result of low-grade bacterial infection of the disk space.[3,5,6,17,18] Some investigators think that intervertebral disk inflammation is noninfectious and the result of antecedent trauma to the spine.[19]

Most blood culture results obtained from patients with diskitis are negative. If positive, *Staphylococcus aureus* is the most common isolate (Table 78.1). Other organisms isolated from blood cultures or disk aspirates from affected children have included *S. epidermidis*,[20] *Kingella kingae*,[2,15,21–25] anaerobes,[26] gram-negative enteric organisms,[20,26–28] *Streptococcus pneumoniae*,[5] and *Brucella* species.[29] In most cases, cultures of intervertebral disk specimens are sterile (Table 78.2).

TABLE 78.1

Results of Blood Cultures for Children With Diskitis

Study	No. of Patients	Blood Cultures	
		No. of Cultures	No. of Positive Results
Smith and Taylor (1967)[13]	20	24	0
Wenger et al. (1978)[6]	41	22	10[a]
Scoles and Quinn (1982)[28]	29	9	0
Crawford et al. (1991)[47]	36	28	2[b]

Brown et al. (2001)[48]	11	11	0

[a] *Staphylococcus* aureus (9 results); diphtheroids (1 result).

[b] *Staphylococcus aureus* (2 results).

TABLE 78.2

Results of Disk Space Aspirates for Children With Diskitis

Study	No. of Patients	No. of Biopsies or Aspirates	No. of Positive Culture Results
Smith and Taylor (1967)[13]	20	3	1/3[a]
Spiegel et al. (1972)[5]	48	15	5/15[b]
Wenger et al. (1978)[6]	41	9	6/9[c]
Scoles and Quinn	29	6	2/6[d]

(1982)[28]			
du Lac et al. (1990)[9]	12	8	6/8[e]
Crawford et al. (1991)[47]	36	3	0/3
Ryoppy et al. (1993)[12]	18	17	0/17
Brown et al. (2001)[48]	11	3	0/3
Garron et al. (2002)[2]	42	35	22/35[f]

[a] *Staphylococcus aureus* (1 result).

[b] *Moraxella* spp., *Staphylococcus aureus*, *Streptococcus pneumoniae*, diphtheroids, and micrococcus (1 result each).

[c] *Staphylococcus aureus* (6 results; 1 also showed α-hemolytic *Streptococcus*).

[d] *Klebsiella* spp. and *Staphylococcus aureus* (1 result each).

[e] *Moraxella* spp. (1 result) and *Staphylococcus aureus* (5 results).

[f] *Staphylococcus aureus* (12 results), *Kingella kingae* (6 results), *Staphylococcus epidermidis* (1 result), *Clostridium clostridiiforme* (1 result), *Streptococcus* spp. (1 result), and *Coxiella burnetii* (1 result).

Viruses have not been isolated from disk space cultures. *Mycobacterium* species and *Candida* species have been isolated by disk space aspiration from older adults.[30]

Pathogenesis and Pathologic Findings

The lumbar or lower thoracic spine is involved in most cases.[31] There are rare reports of diskitis involving the cervical spine.[28,32] Usually only one disk space is involved, although patients with involvement of two intervertebral disk spaces have been reported.[13]

The difference in blood supply to the vertebral bodies and disk spaces in children compared with adults may explain the age-related incidence of diskitis.[33–35] In the young child, there are widespread anastomoses between intraosseous arteries supplying the vertebrae. These vessels begin to involute at about 8 months of age and are few in number by the age of 7 years. By the third decade of life, the anastomoses have atrophied fully, and peripheral periosteal arteries develop. As a result of this rich blood supply to the vertebral end plates, a septic embolus in a child leads only to small areas of vertebral end plate infarction or infection, with disproportionate involvement of the intervertebral disk. A septic embolus in an adult results in a much larger area of vertebral body infarction and subsequent infection, which causes vertebral osteomyelitis.[1,33]

The intervertebral disk is composed of the cartilaginous plate, the annulus fibrosus, and the nucleus pulposus.[36] Examinations of cadavers have demonstrated that blood vessels exist in the cartilaginous end plates until 7 years of age and in the annulus fibrosus until 20 years of age.[34] This may explain the finding of disk space inflammation or infection with relative sparing of the vertebral body that is seen in children. An ovine animal model of diskitis demonstrates that infection of the disk impedes disk development but does not seem to affect vertebral body growth.[37]

Magnetic resonance imaging (MRI) findings in children with diskitis suggest a pathophysiologic sequence in which infection or inflammation begins in the metaphyseal bone near the vertebral endplates, with anterior spread to the disk region and the adjacent vertebral end plate.[4,38] Histologic examination of disk biopsy specimens from children with diskitis reveals subacute or chronic nonspecific inflammation. For some children with the characteristic clinical and radiologic findings of diskitis, histologic results are normal.[5,12]

Clinical Manifestations

The clinical manifestations of diskitis depend on the age of the child.[5,6,9,11,13,28] Onset is gradual, with symptoms often existing for several days to weeks before the child comes to medical attention. Younger children are more likely to have a history of irritability and reluctance to walk or bear weight.[39] Older children complain of back pain, hip pain, abdominal pain, or pain with walking. Some patients have abdominal complaints such as anorexia, vomiting, abdominal pain, and constipation (Table 78.3).

TABLE 78.3

Frequency of Presenting Symptoms in 165 Patients With Diskitis

Symptoms	Percentage of Patients
Limp, leg pain, or refusal to walk[a]	41
Back pain	41
Abdominal pain	15

[a] Children whose presenting symptom was refusal to bear weight or walk were younger (≥5 yr) when they came to medical attention.

Data from references 5, 6, 20, 28, 41, and 47.

On physical examination, the child often has a low-grade fever but appears well. Comfortable when lying still, the child refuses to bear weight or walks with a limp. Irritability with sitting or flexion of hips and pain with palpation over the lower back are common. The paraspinous muscles can spasm. The normal curvature of the spine sometimes can be altered, with loss of normal lumbar lordosis.[10,20,40,41] Gower sign (i.e., use of a hand push-off rather than use of the pelvic girdle to rise from sitting) can be seen in children with diskitis; it disappears after treatment.[42,43]

Abnormal neurologic findings are uncommon, but one retrospective case series described decreased muscle tone, muscle weakness, and decreased tendon reflexes in 7 of 17 children diagnosed with diskitis.[44] Neurologic abnormalities therefore do not exclude a diagnosis of diskitis. However, when detected, imaging studies are needed to exclude intraspinal involvement or an alternative diagnosis. Failure to consider a diagnosis of diskitis, to examine the lower back carefully, and to order the appropriate radiologic studies often results in delay in diagnosis and inappropriate use of tests.[45]

Differential Diagnosis

The differential diagnosis of diskitis includes vertebral osteomyelitis or osteomyelitis of the pelvis, pyogenic arthritis of the hip or sacroiliac joint, abscess of the psoas muscle or pelvic structures, spinal epidural abscess, meningitis, appendicitis, malignant processes, pyelonephritis, and tuberculosis of the spine. If a child appears to be ill and has a high fever, marked leukocytosis, neurologic abnormalities, or extensive involvement of the vertebral body, diskitis is not the likely diagnosis.[46] An immediate workup to rule out a more serious cause of symptoms should be initiated.

Diagnosis

The erythrocyte sedimentation rate (ESR) is typically elevated (rarely to more than 60 mm/hr) in children with diskitis.[10,11,28] The peripheral white blood cell (WBC) count is normal or slightly elevated.[11,47] The C-reactive protein (CRP) level can be elevated.[48] When a blood culture is obtained, the result usually is negative. A skin test for tuberculosis and chest radiograph are useful in circumstances in which tuberculosis is possible. When culture results are positive, therapy can be targeted to the causative pathogen.

Early in the course of diskitis, findings on plain radiography of the spine may be normal. Between 2 and 4 weeks after the onset of symptoms, the involved disk space is narrow, and the margins of the vertebral end plates exhibit demineralization and irregularity (Fig. 78.1). At 2 to 3 months after onset of symptoms, the disk space remains narrow, and remineralization of vertebral end plates has occurred. Long-term follow-up in most patients shows persistence of a narrow disk space and sclerotic changes at the vertebral end plates (Fig. 78.2). In some cases, involved vertebral bodies become fused or their shapes change.[10,11, 28,49,50]

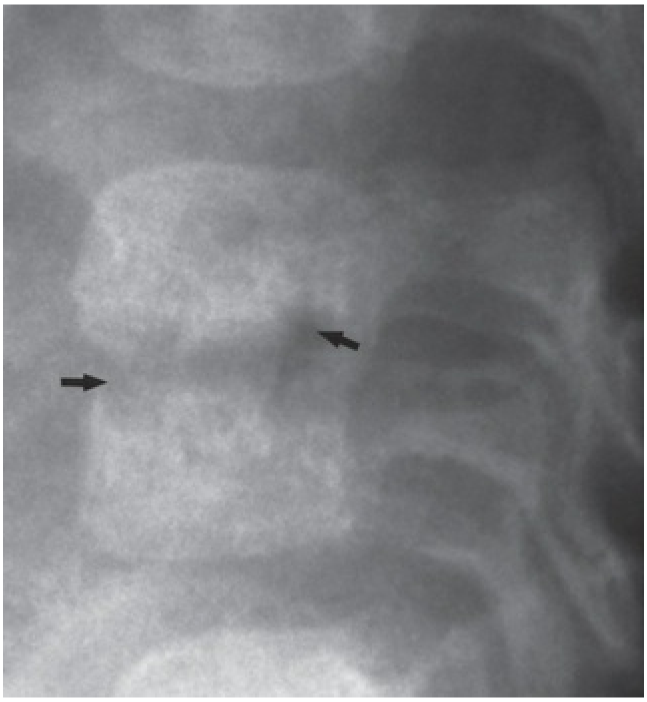

FIGURE 78.1 Diskitis involves the L4 to L5 space in an 18-month-old girl. Notice the narrowed disk space and irregularities of the adjacent vertebral end plates.

(Courtesy of Bruce Parker, MD, Palo Alto, CA.)

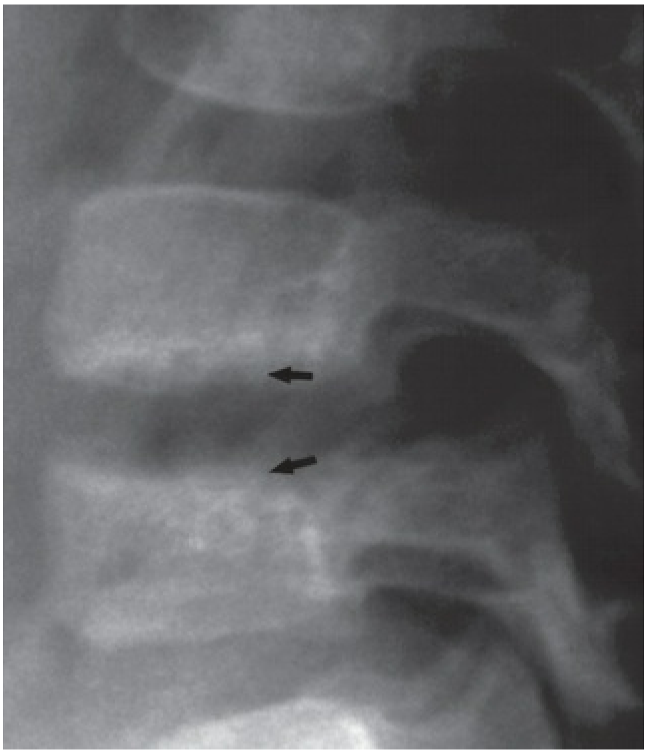

FIGURE 78.2 Follow-up radiograph of the same patient as in Fig. 78.1 was obtained 6 months after onset of symptoms. Some narrowing of disk space persists. Notice the sclerotic changes of the adjacent vertebral end plates. (Courtesy of Bruce Parker, MD, Palo Alto, CA.)

Other imaging modalities are useful if plain radiographic results are normal. Technetium bone scan has been used and frequently shows increased uptake at the disk space.[40,47] Computed tomography (CT) can demonstrate narrowing of the disk space and vertebral body involvement early in the course of disease.[20] MRI is the most sensitive technique for confirming the diagnosis of diskitis.[4,9,37,41,51] MRI is particularly useful for detecting paravertebral abscess, epidural abscess, severe protrusion of the disk, or significant vertebral body involvement.[48,52]

Aspiration of the disk space for culture in cases with compatible clinical findings and supportive imaging is controversial. Some investigators have reported a good yield from culture of material obtained from aspiration.[9,17,18] Identification of an organism, especially an unusual one such as *K. kingae,* may affect the choice of therapy. In many studies, most aspirates from a disk space are sterile even when antibiotics have not been administered.[5,13,28,47] Aspiration of the disk space therefore may be limited to cases in which there is no response to immobilization or empiric antibiotic therapy, cases with extensive involvement of the vertebral body, or cases that have other atypical features.[3,13,27,30,47] An aspirate or biopsy specimen of the disk space should be cultured for bacteria, mycobacteria, and fungus.

Management

Most children with diskitis respond promptly to bed rest, with decreased pain within 48 hours. Immobilization of the spine sometimes is required. Failure to respond to immobilization suggests that the diagnosis is incorrect. The optimal duration of immobilization is unknown. There has been no study correlating long-term outcome and duration of immobilization.

Some investigators suggest the use of antibiotic therapy only if culture results are positive or the child appears to be systemically ill or has not responded promptly to immobilization.[5,12,25,28,40,47] Although antibiotic therapy for diskitis does not appear to alter the long-term prognosis, one retrospective analysis of 47 patients showed that use of a short course of parenterally administered antibiotic agents followed by oral therapy hastened resolution of symptoms.[4] Because several cases have been associated with positive culture results, particularly for *S. aureus,* antibiotic treatment for an arbitrary length of time seems prudent.[1,3,4,6] In the absence of a positive culture result, empiric therapy for staphylococci and *K. kingae* is appropriate. Antibiotic agents can be administered intravenously for several days, until fever and pain have resolved and the ESR is decreasing, and then given orally. Optimal duration of therapy is unknown, but it should be continued until the patient is asymptomatic and the ESR or CRP level is normalizing.

Outcome

Most children with diskitis have persistently abnormal radiographic findings long after clinical symptoms have resolved.[12,37,49] The involved disk space may never regain its original height, and sclerotic changes in the vertebral end plates persist. Cases of recurrent symptoms have been reported.[5] Although reports of follow-up of patients with diskitis have included small numbers of patients and relatively short periods, most patients are asymptomatic and have no limitation of activity.[5,6,12,53] Younger children appear to have a lower rate of bony ankylosis compared with older children, presumably because of the increased vascular channels that promote more rapid healing.[53]

Some patients have mild, chronic back pain.[12,40] A study of 35 patients who were followed for an average of 17 years found that 42% complained of persistent backache. Extension of the spine was restricted in 30 patients. Most patients had been treated with bed rest or with a lengthy course of antibiotic agents and immobilization.[50]

Transient Synovitis

C. Buddy Creech

Transient synovitis (TS) is a self-limited inflammation of the synovium, usually of the hip joint. TS is a common cause of limp in childhood. Synonyms for this condition include toxic synovitis, observation hip, irritable hip, and benign aseptic arthritis.[1–4]

Etiology and Epidemiology

The cause of TS is unknown. In the few cases for which biopsy specimens of the synovial membrane have been obtained, histologic examination shows nonspecific inflammation.[5,6] Considering that many children with TS have had a recent or concurrent upper respiratory or gastrointestinal viral infection and that elevated serum interferon levels have been demonstrated in some patients, TS likely represents a self-limited infection involving the synovial membrane or a postinfectious inflammatory response.[7–9]

Some investigators have found positive throat culture results for group A *Streptococcus* or elevated antistreptolysin O (ASO) titers, or both, for a small number of children with toxic synovitis.[8,10] However, no single organism has been implicated consistently as the cause of TS. In one series, an increase in antibody concentrations against rubella, enterovirus, Epstein-Barr virus, or *Mycoplasma* was demonstrated for 67 of 80 children with TS, but there was no unaffected control group; results of viral culture for synovial fluid were negative; and culture samples were not obtained from other sites.[11] In other reports, including one prospective study in which a control group was included and one study in which serologic evidence of acute parvovirus B19 or human herpesvirus 6 infection was sought, no evidence of viral or streptococcal causes was found.[5,12–15] Parvovirus B19 DNA has been detected by polymerase chain reaction (PCR) in the sera of a small number of children with TS.[16]

TS occurs predominantly in children 18 months to 12 years of age; in various studies, the mean age of occurrence is 5.6 to 5.9 years.[3,12,14,17] Boys are affected approximately twice as often as girls.[3,8,12,14,15,17–19] Although the annual incidence in the United States is unknown, TS frequently is referred to as the most common cause of hip pain in children.[20] The average annual incidence in one study of Swedish children was 0.2%.[19]

Clinical Manifestations

The usual manifestation of TS is acute onset of leg pain or limp in an otherwise healthy child. Symptoms are typically unilateral, with right and left hips affected equally. There have been rare reports of children with involvement of both hips.[3,12]

Leg pain can be localized to the hip, thigh, or knee. The intensity of pain ranges from mild to severe enough to awaken the child.[2,19] Most children are afebrile or have minimal temperature elevation.[21,22] The child usually appears minimally ill, with pain on movement of the knee, thigh, or hip on the affected side and limited internal rotation and adduction of the affected hip.[3,8]

The duration of symptoms ranges from 1 day to 3 weeks. Most children become asymptomatic approximately 1 week after the onset of symptoms.[13,14,23] Prolonged hip pain suggests another diagnosis.

Diagnosis

Laboratory and imaging studies can help to differentiate TS from more serious causes of hip pain. The white blood cell (WBC) count usually is normal, and the erythrocyte sedimentation rate (ESR) is normal or mildly elevated (<30 mm/hr). The mean C-reactive protein (CRP) level in one study of 64 patients with TS was 1.0

mg/dL.[24] Inflammatory markers for pyogenic (bacterial) arthritis and TS can overlap.[22,24] Blood and joint fluid cultures are helpful because a positive bacterial culture rules out TS.

Plain radiographs of the pelvis and hip often are normal.[18,19,25] They are obtained to rule out osteomyelitis, cancer, or Legg-Calvé-Perthes (LCP) disease.[10,25,26]

Ultrasound (US) is a useful noninvasive method for delineating the joint effusion[23,27–30] found in approximately 70% of children with TS.[12] US is helpful in guiding joint aspiration, particularly in children younger than 8 years, because cartilaginous structures are visualized well. In older children, fluoroscopic guidance is the preferred approach.[26] The bone scan is normal or shows increased uptake, especially in the blood pool phase.[31–33]

Magnetic resonance imaging (MRI) results are normal or reveal abnormal thickening of the articular surfaces and joint effusion.[34,35] Signal intensity alterations detected by MRI in bone marrow may help differentiate pyogenic arthritis from TS. Low-signal-intensity alterations on fat-suppressed T1-weighted images and high-signal-intensity alterations on fat-suppressed T2-weighted images are seen in the bone marrow of the affected joint in many of patients with bacterial arthritis and not seen in patients with TS.[36,37]

Differential Diagnosis

TS is a diagnosis of exclusion.[9,19] The differential diagnosis includes bacterial arthritis of the hip; osteomyelitis of the proximal femur, acetabulum, or sacroiliac joint; pyomyositis; psoas muscle or intra-abdominal abscess; trauma; pauciarticular arthritis; rheumatic fever; malignant tumor; slipped capital femoral epiphysis; LCP disease; fracture; and reactive arthritis.

Early differentiation of TS from bacterial arthritis of the hip is crucial because delay in surgical decompression for pyogenic arthritis can result in increased morbidity.[21,22] An evidence-based clinical prediction algorithm using four independent multivariate predictors (i.e. fever ≥38.5°C, refusal to bear weight, ESR >40 mm/hr, and peripheral WBC count >12,000 cells/mm^3) was proposed by Kocher and colleagues to estimate the probability of pyogenic arthritis.[38] Three or four predictors had a positive predictive value (PPV) for pyogenic arthritis of 93% or 99.6%

respectively, and one or two criteria had a PPV of 3% or 40%, respectively.[38] For a new cohort of children studied prospectively by the same investigators, performance of the algorithm was not as strong. In the prospective cohort, the area under the receiver operating characteristic curve was 0.86, compared with 0.96 in the original study.[39]

In a subsequent study of five independent clinical and laboratory markers (i.e., temperature >37°C, ESR >20 mm/hr, CRP ≥2 mg/dL, WBC >11,000 cells/mm^3, and difference of joint space distance >2 mm), identification of four predictors had a PPV for pyogenic arthritis of 99%; no or one predictor had PPV of 0.1% to 1.7%.[40]

A prospective study using the variables in the Kocher algorithm in addition to the CRP value found that fever was the best predictor of pyogenic arthritis, followed by an elevated CRP level, elevated ESR, refusal to bear weight, and an elevated WBC count.[41] In contrast, in a retrospective study of 311 children with hip effusion, a CRP >20 mg/L was the strongest independent risk factor for septic arthritis.[42]

In a retrospective application of five factors (with temperature ≥38.5°C, ESR ≥40 mm/hr, and CRP ≥2 mg/dL) in a general hospital, a finding of all five factors had a PPV of 60%, and fever was the single best predictor.[43] It is important to consider that the validity of clinical prediction algorithms can vary substantially between institutions and that no clinical prediction rule has been validated by large, prospective studies in different populations.[44–46]

Aspiration of fluid from the joint space frequently is attempted in patients with suspected TS because this is the most reliable method of excluding the diagnosis of pyogenic arthritis. The procedure also relieves pain. In cases of TS, the fluid is expected to be clear or slightly turbid, usually with a volume of less than 5 mL containing less than 1000 WBC/mm^3.

LCP disease frequently manifests as a limp in an otherwise healthy 5- to 9-year-old, afebrile child who has a normal peripheral WBC count and ESR. Boys are affected four times more often than girls. Initially, the clinical features, laboratory test results, and US findings may be indistinguishable from findings in TS. Plain films, bone scan, and MRI are useful differentiating tests; LCP disease shows ischemic necrosis of the head of the femur.[18,26,32,34,47] In children with LCP disease, bone age often is delayed from 6 months to 3 years.[2]

Treatment and Prognosis

Treatment of TS of the hip is rest. The usual duration of symptoms is 5 to 7 days. One small, double-blind, placebo-controlled trial of ibuprofen versus placebo demonstrated that ibuprofen shortened the duration of symptoms from 4.5 to 2 days in children with TS.[48] Close follow-up is necessary to detect development of signs and symptoms of pyogenic arthritis or osteomyelitis, which may be more challenging if patients have received anti-inflammatory drugs.

Children who are older than 6 years or who have protracted symptoms require careful evaluation and follow-up to differentiate LCP disease from other disorders. Some investigators suggest that children with TS are at higher risk for LCP disease,[7,9,18] whereas others have found no relationship between the two entities other than the similarity in initial clinical presentation.[14]

TS is self-limited and resolves with supportive therapy. Symptoms recur in a small number of children.[5,8,9] In some series, up to 30% of children who were followed for 1 to 30 years after an initial episode developed asymptomatic overgrowth (i.e., coxa magna) of the femoral head.[1,17] The long-term significance of this finding is unknown.

Conjunctivitis in the Neonatal Period (Ophthalmia Neonatorum)

Douglas R. Fredrick

Ophthalmia neonatorum is defined as conjunctivitis occurring within the first month of life. It is the most common eye disease of neonates, with an incidence ranging from 1.6% to 12%.[1–3] Incidence is directly related to the prevalence of sexually transmitted infection (STI) in adults. One hundred years ago, *Neisseria gonorrhoeae* was the most common pathogen and a major cause of blindness among children. With the advent of Credé prophylaxis (instillation of silver nitrate at time of birth) and changing trends in STI, *Chlamydia trachomatis* has become the most common sexually transmitted pathogen (Table 80.1).[4–14] In general, offspring of women who receive prenatal care have a lower incidence of infectious conjunctivitis.[12–14] In the absence of maternal STI, neonatal conjunctivitis is acquired postnatally and is caused by *Staphylococcus aureus, Streptococcus pneumoniae, Haemophilus* spp., and viridans streptococci. Viruses, with the exception of herpes simplex virus (HSV), are less common pathogens in this age group.

[a] Percentages represent approximations because most studies show total number of isolates, and multiple isolates were recovered from individual patients.

[b] Excludes coagulase-negative staphylococci, *Corynebacterium* spp., *Propionibacterium acnes*, and diphtheroids.

[c] US (references 6, 7, 8, and 10), United Kingdom (reference 2), Sweden (reference 11), Belgium (reference 12).

[d] Other bacterial pathogens not stated.

Hospital-associated infection can occur in neonatal intensive care units due to *S. aureus*, gram-negative bacilli (especially *Pseudomonas aeruginosa*), and adenovirus. Significant predictors of conjunctivitis include low birth weight, use of ventilator or nasal cannula, and continuous positive airway pressue.[15] Ophthalmologic examination has been associated with nosocomial bacterial conjunctivitis, and most notably adenovirus conjunctivitis (sometimes with dissemination and fatal outcome).[15,16]

Pathogenesis

Microbial pathogens can be transmitted to the eye by a variety of routes. Premature rupture of placental membranes allows for the retrograde spread of organisms to the fetal conjunctiva and cornea. Hematogenous spread can occur transplacentally as well. During vaginal delivery, the neonate's eyes can become infected by contact with infected maternal genital secretions. After birth, caregivers can transmit pathogens to the neonate's eyes through direct contact or aerosolization.

In addition to the immaturity of the immune system, the neonate has local risk factors for ocular infections. The secretory rate of tears under basal conditions in premature infants is about 20% of that in full-term infants,[17] and the blink frequency is decreased. The concentration of lysozyme, the enzyme in tears that catalyzes the breakdown of the bacterial cell wall, also is diminished in premature infants compared with full-term infants and adults.[18] A final reason for increased susceptibility of the neonatal eye is a lack of secretory immunoglobulin A (IgA) in the tears of neonates.[19]

Etiologic Agents

Chlamydia Trachomatis

Epidemiology

C. trachomatis has been the most common cause of infective neonatal conjunctivitis (see Table 80.1). Frequency of conjunctivitis reflects the prevalence of maternal genital infections, ranging from 18% to 23%.[20,21] The likelihood of transmission from untreated infected mothers to infants ranges from 18% to 61% (Table 80.2).[22–28]

TABLE 80.2

Prevalence of Chlamydial Conjunctivitis Among Infants Born to Mothers With Chlamydial Cervicitis

Country of Study	No. of Infants	Neonates Infected (%)	Reference
United States	18	44	22
United States	18	61	23
Sweden	23	22	24
United States	60	20	25
United States	95	28	20
United States	131	18	27
United States	120	25	28
Kenya	201	31	13

Clinical Manifestations

Chlamydial conjunctivitis is usually clinically evident within 5 to 14 days of birth, although it can appear as early as 3 days, especially after premature rupture of membranes, or as late as 60 days.[22,29] Typical findings are eyelid swelling, erythema, and unilateral or bilateral mucopurulent conjunctivitis; the cornea usually is not involved. On occasion, pseudomembranes and (rarely) true membranes develop. The expected lymphoid follicular response of the conjunctiva does not appear unless the infection persists beyond 6 weeks of age. In treated cases, healing usually occurs without sequelae. Infection in untreated or inadequately treated cases can persist for 2 to 12 months, and some cases remain clinically apparent for years. Persistent infection can lead to conjunctival scar formation and corneal micropannus.[30,31]

The major nonocular complication of chlamydial conjunctivitis is pneumonia. Pneumonia develops in 11% to 20% of infected infants and typically manifests at 1 to 3 months of age.[29,32,33] Infants usually are afebrile but have nasal congestion, prolonged cough, tachypnea, and rales. Hyperinflation with interstitial or alveolar infiltrates is evident radiographically. Total serum IgG and IgM antibody values are elevated, and eosinophilia sometimes occurs. Antibodies to *C. trachomatis* are detectable in tears and serum. Although infection usually is self-limited, systemic treatment is recommended because it shortens the duration of ocular and respiratory tract illness and because treatment of ocular infection prevents pneumonia.[33–35]

Diagnosis

In the past, *C. trachomatis* conjunctivitis was diagnosed by Giemsa staining of conjunctival scrapings showing blue-stained intracytoplasmic inclusions within epithelial cells. The sensitivity of Giemsa staining ranges widely, from 22% to 95%, reflecting varied technical and examiner skill.[5,6,36] Staining has been replaced by use of nucleic acid amplification test (NAAT) performed on conjunctival swabs. These tests are available widely and provide rapid results with high sensitivity.[37] Organism detection by direct fluorescence has lower sensitivity and is difficult to standardize but is less costly.[8,38–42] Cultivation of organisms in yolk sac or tissue culture is a sensitive means of confirming the diagnosis, but these techniques are laborious and slow and are used only in special circumstances.

Treatment

Systemic therapy for conjunctivitis due to *C. trachomatis* is recommended in all cases to treat conjunctivitis and prevent pneumonia.[26] Erythromycin estolate or ethylsuccinate, 50 mg/kg/day in 4 divided doses for 14 days, is curative in about 80% of cases.[34] A short course of azithromycin (20 mg/kg), given as a single dose or daily for 3 days, also may be effective and may be less associated with idiopathic hypertrophic pyloric stenosis.[25] Topical corticosteroid therapy is contraindicated because it can prolong the infection and possibly lead to conjunctival scarring.

Neisseria Gonorrhoeae

Epidemiology

In the past, *N. gonorrhoeae* was the most serious cause of ophthalmia neonatorum because of this organism's capacity to damage the eye; this infection accounted for 24% of children enrolled in schools for the blind between 1906 and 1911.[43] After the widespread use of perinatal ocular prophylaxis, the incidence of gonococcal ophthalmia neonatorum decreased, and the proportion of admissions to schools for the blind as a result of this infection dropped to 0.6% by 1959. In the United States, the emergence of penicillin-resistant gonococci and the increase in frequency of asymptomatic genital gonococcal infection resulted in a higher prevalence of infections in the 1970s.[44,45] In the US and England currently, neonatal gonococcal ophthalmia is rare.[46] In developing countries, the estimated incidence of gonococcal ophthalmia neonatorum is much higher than in the US, ranging from 15% to 34%. In Kenya, where ocular prophylaxis was discontinued in the mid-1970s and the prevalence of penicillinase-producing *N. gonorrhoeae* has risen to 60%, gonococcal ophthalmia has reached epidemic proportions.[9]

Clinical Manifestations

The clinical manifestations of gonococcal ophthalmia neonatorum typically appear 2 to 7 days after birth, although initial manifestations in the second week are not uncommon (Table 80.3). Later onset suggests postnatal exposure to the organism. Most neonates have edema of the eyelid and purulent conjunctivitis; however, some have a mild or catarrhal response.[47] The inflammatory response of the external ocular surface in infants tends to be less severe than that in the older child or adult. Even with treatment, exudative conjunctivitis can continue for 7 to 14 days before subsiding, contributing to the common complication of conjunctival scarring.

TABLE 80.3

Differential Diagnosis of Neonatal Conjunctivitis

Cause of Conjunctivitis	Time of Onset	Discharge	Corneal Involvement
Chemical	24 hours	Serous	No
Neisseria gonorrhoeae	2–7 days	Mucopurulent	Infiltrate
Chlamydia trachomatis	5–14 days	Mucopurulent	No
Herpes simplex virus	6–14 days	Serous	Dendrite, epithelial ulcer

Corneal involvement is the most serious complication because ulceration with resultant scarring is the major cause of visual impairment.[48] Initially, superficial keratitis gives the corneal surface a dull appearance. Subsequently, marginal and central infiltrates can appear, which then ulcerate, sometimes forming a ring abscess. Corneal perforation leads to abnormal apposition of the iris against the posterior cornea, which can persist as an adherent leukoma. The ulcerated or perforated cornea also can be the portal for invasion by other organisms, resulting in endophthalmitis. Prompt use of antibiotic therapy to treat gonococcal ophthalmia neonatorum can prevent such ocular complications.

Extraocular gonococcal infection may coexist with ocular infection and is more common than previously thought. Fransen and colleagues[9] reported that *N. gonorrhoeae* was isolated from pharyngeal specimens in 15% of infants with gonococcal ophthalmia. Although gonococcal pneumonia is not well documented, pharyngeal colonization can lead to bacteremic spread to distant sites, especially joints.[49,50]

Diagnosis

Gram stain of ocular exudate shows predominance of neutrophils with intracellular gram-negative diplococci. *Moraxella catarrhalis* and *Neisseria meningitidis* can be confused with *N. gonorrhoeae* on Gram stain.[51–54] Diagnosis of gonococcal ophthalmia is confirmed by culture on chocolate agar or Thayer-Martin media incubated at 37°C in humidified carbon dioxide. Appropriate culture specimens also should be obtained from the mother, and testing for *Chlamydia,* syphilis, and HIV should be performed. Blood and cerebrospinal fluid cultures (in an infant who is febrile or otherwise not behaving normally) also are obtained, as are tests for concurrent *C. trachomatis* infection.

Treatment

Neonates with gonococcal ophthalmia should be hospitalized and treated with parenteral therapy; topical therapy alone is ineffective. Because of the increased prevalence of penicillin resistance in *N. gonorrhoeae,* ceftriaxone (25–50 mg/kg, not to exceed 125 mg, is given once intravenously or intramuscularly).[55] Ceftriaxone should not be given to neonates with hyperbilirubinemia; cefotaxime given intravenously or intramuscularly is an alternative.[55] Most infants will be treated parenterally with ceftriaxone (25–50 mg/kg once daily) or cefotaxime (25–50 mg/kg/dose 2 or 3 times daily depending on age <7 or >7 days) until disseminated infections are excluded. In addition, the eye should be irrigated with saline solution at first hourly and then every 2 to 3 hours until discharge is eliminated. Instillation of topical antibiotic is not necessary after diagnosis is confirmed and appropriate systemic antibiotic therapy has been initiated. It is imperative that the mother of the child and all sexual partners be referred for testing for *Chlamydia* and other sexually transmitted infections. Gonococcal infections are designated as a notifiable disease.

Herpes Simplex Virus

Epidemiology

HSV can infect and seriously damage a neonate's eye. Before the availability of antiviral therapy, many infants with isolated perinatally acquired herpetic conjunctivitis or skin or other mucous membrane infection progressed to more serious infection.[56,57] Most neonatal infections are caused by HSV type 2, which has an estimated prevalence of nearly 25% among adults in the US.[58]

Clinical Manifestations

Ophthalmia neonatorum due to HSV typically becomes evident 6 to

14 days after birth, although infants born after prolonged rupture of placental membranes can have manifestations at birth.[59] Conjunctivitis, which can be unilateral or bilateral, is associated with ipsilateral eyelid edema and serous discharge. In the absence of herpetic lesions of the cornea or skin, herpetic conjunctivitis is indistinguishable from ophthalmia from other causes. Depending on the duration and severity of infection, examination of the cornea can reveal superficial keratitis, epithelial dendrite, geographic ulcer, or disciform stromal keratitis.[60] Although keratoconjunctivitis can be the sole manifestation of HSV infection in the neonate, it more commonly appears in association with other manifestations of systemic infections.[56,57] Most corneal infections in the neonate are detected with the use of a speculum to hold the eyelids apart and a cobalt blue light to illuminate the corneal surface, stained with a fluorescent dye.

Diagnosis

The diagnosis of HSV infection is confirmed by culture of specimens obtained from skin vesicles or conjunctival or corneal lesions. Plasma polymerase chain reaction (PCR) assay also can aid diagnosis. All neonates in whom HIV infection is suspected should undergo lumbar puncture and CSF testing for HSV DNA using PCR. Direct immunofluorescence assay or enzyme immunoassays also can be performed on swabs from the conjunctiva, but their sensitivity and specificity rates are lower than those of PCR.

Treatment

All infections caused by HSV in the neonatal period are treated with systemically administered acyclovir (60 mg/kg/day in three divided doses intravenously for 14 days; duration may be longer if other sites are involved. Keratoconjunctivitis usually responds to systemic treatment but may require the addition of topical therapy (1% trifluridine, 0.1% iododeoxyuridine, or 0.15% ganciclovir). Topical cycloplegics are indicated for relief of ciliary spasm if keratitis is present. Topical corticosteroid agents should be avoided because they may augment corneal damage.

Other Infectious Causes

The predominant bacterial pathogens recovered from young infants with nonchlamydial, nongonococcal conjunctivitis include *Haemophilus influenzae, Streptococcus pneumoniae,* and coagulase-negative staphylococci (CoNS) (see Table 80.1).[2–6,8–12,14,61] Although less common, various gram-negative organisms, such as *Escherichia coli, Klebsiella pneumoniae,* and *Pseudomonas aeruginosa* (especially in nosocomial settings), and *Neisseria cinerea,* collectively account for a sizable proportion of cases of conjunctivitis. Isolation of these bacteria from conjunctival specimens is not a priori evidence of causation. Demonstration of neutrophils and a single bacteria organism (especially when also present intracellularly) supports a pathogenic role.

Staphylococci have been implicated in ophthalmia neonatorum, but in most cases it is unclear whether the organisms resided on the conjunctiva or the eyelid (where CoNS is normal flora).[62,63] *S. aureus* can be acquired vertically or postnatally from the skin or nares of hospital personnel or from family members. Infection usually manifests as mild catarrhal conjunctivitis with mucoid or mucopurulent discharge. Potential ocular complication of such as corneal infiltrates and ulcers is perforation and resulting endophthalmitis. Systemic complications include infection at contiguous or distant sites (sinusitis, pneumonia, osteomyelitis, septicemia) or toxin-mediated disease (scalded-skin syndrome).[64] Localized staphylococcal conjunctivitis in a well infant can be treated with topical erythromycin, bacitracin ointment, or polymyxin B–trimethoprim eye drops. Susceptibility tests should be performed as community-associated and hospital-associated *S. aureus* can be multiply resistant.

P. aeruginosa is a rare but important cause of conjunctivitis in hospitalized infants. Prematurity, ventilatory support, and receipt of systemic antibiotic therapy are risk factors. Conjunctivitis can be self-limited and associated with moderate discharge or can progress rapidly, resulting in corneal abscess and endophthalmitis followed by septicemia and death.[65–67] The diagnosis should be suspected when Gram stain of exudate reveals slender gram-negative bacilli. Treatment is topical tobramycin drops, initially instilled every 3 hours. Some experts advocate the addition of subconjunctival tobramycin because of its high intraocular penetration.[68] Lack of response to therapy or progression to endophthalmitis, or periocular infection, requires systemic or intraocular antibiotic therapy, or both (see Chapter 84).

Prophylaxis

In 1881, Credé introduced ocular prophylaxis, consisting of cleansing of the eyelids immediately after birth followed by instillation of 2% silver nitrate drops into the conjunctival sac. Combined results of 24 studies conducted in North America and Europe between 1930 and 1979 indicated that only 0.06% of infants receiving topical silver nitrate experienced gonococcal ophthalmia.[69] Reported incidence was similar in the US among 12,431 infants born between 1986 and 1988.[70] However, use of silver nitrate is limited by its failure to prevent all cases of gonococcal ophthalmia,[71–73] chemical conjunctivitis, and corneal scarring after inadvertent use of a high concentration of silver nitrate. Silver nitrate is no longer available in most countries. Changes in the epidemiology of ophthalmia to a predominance of *C. trachomatis* in the early 1970s, however, prompted consideration of alternate prophylactic strategies.[74] Topical erythromycin and tetracycline were proposed because of their activity against *C. trachomatis*.[24] Two US studies have shown that, although silver nitrate, erythromycin, and tetracycline preparations are each effective prophylaxis against gonococcal ophthalmia, none prevents chlamydial ophthalmia.[13,70]

The American Academy of Pediatrics and the Centers for Disease Control and Prevention recommend the use of 1% tetracycline ointment or 0.5% erythromycin ointment for prophylaxis against *N. gonorrhoeae*.[55] Although this treatment is highly effective when administered properly and within 1 hour of birth, infants born to mothers with active infection also should be treated with a single dose of ceftriaxone given intravenously or intramuscularly (25–50 mg/kg; maximal dose 125 mg).[55] In developing countries, a single application of a 2.5% solution of povidone-iodine can be considered for ocular prophylaxis because it is inexpensive and has been shown to be more effective and less toxic than erythromycin and silver nitrate.[75] A second application of 2.5% povidone-iodine was found to be no more efficacious than a single application.[76] Reducing STIs and treating infected mothers before parturition are the best means of preventing infection in neonates.[77] As the incidence of neonatal conjunctivitis has decreased, several European countries have dropped their recommendation for antibiotic prophylaxis, and others have advocated abandoning routine prophylaxis with erythromycin because the incidence of resistance can be as high as 25%.[78] With concerns of underreporting and because the risk for treatment is low and consequences of infection from gonococcus substantial, routine prophylaxis continues to be recommended in the US.[79–80]

Key Points

Diagnosis and Management of Neonatal Conjunctivitis

Epidemiology

- Conjunctivitis occurring in infant in first 28 days of life
- Incidence 1%–12%; more common in developing countries where mothers do not receive prenatal care
- Risk for infant infection when mother has active gonorrhea is about 28%.
- Risk for infant infection when mother has active *Chlamydia* infection is up to 50%.
- In mothers who have received prenatal care and testing, most cases are due to *Staphylococcus, Streptococcus, Haemophilus,* and gram-negative species.

Clinical Features

- *Neisseria gonorrhea* manifests usually with hyperacute copious mucopurulent discharge between 2 and 7 days of age.
  - Can rapidly lead to corneal perforation if not treated
- *Chlamydia trachomatis* manifests with mucoid discharge between 5 and 14 days of age.

▪ If untreated, infants may develop pneumonia.

- HSV can manifest with or without corneal involvement and less mucoid discharge, characteristically between 6 and 14 days of age.

Diagnosis

- Swab for Gram stain, culture, and susceptibility testing
- Swab for *Chlamydia* culture, nucleic acid amplification test, or PCR
- Swab for HSV PCR assay if clinical suspicion (plus CSF and plasma PCR)

Treatment

- *Neisseria gonorrhoeae:* hospitalization and systemic ceftriaxone or cefotaxime plus very frequent irrigation
- *Chlamydia trachomatis:* erythromycin 50 mg/kg/day orally for 14 days
- Bacterial infection: polymyxin B−trimethoprim solution or polybacterial ointment applied topically; systemic therapy depending on clinical findings
- Must test mother for other STIs and report positive cases to public health officials

CSF, cerebrospinal fluid; HSV, herpes simplex virus; PCR, polymerase chain reaction; STI, sexually transmitted infection.

Conjunctivitis Beyond the Neonatal Period

Douglas R. Fredrick

Conjunctivitis is the most common infectious disease of the eye in childhood. It is useful to separate conjunctivitis into acute infection (abrupt onset, lasting less than 10 to 14 days) and chronic infection (insidious onset, often persisting for several weeks, months, or even years). Most cases of acute conjunctivitis are self-limited and can be managed by primary care providers. Evaluation and successful management of chronic conjunctivitis, however, usually require consultation with an ophthalmologist for specialized diagnostic techniques and to prevent eventual vision-threatening damage.

Microorganisms can be transmitted to the ocular surface in a number of ways, but direct contact with contaminated fingers is the most common. Bacterial pathogens usually are found in nasopharyngeal secretions as well. Viral pathogens have specific tissue tropism, some rarely affecting conjunctival mucosa (e.g., influenza, respiratory syncytial virus), with others having a proclivity for conjunctival mucosa (e.g., adenovirus, herpes simplex). Organisms can be inoculated into the conjunctiva by airborne droplets produced by coughing and sneezing and, because many viruses can remain viable on dry surfaces for several hours, infection can result from exposure to infected fomites. Vector-borne ocular infections occur in some developing countries. For example, the filarial parasite *Onchocerca volvulus* is transmitted to the eye by the bite of an infested blackfly.

Conjunctivitis is a clinical diagnosis based on the presence of conjunctival hyperemia and ocular discharge. Typically, the palpebral conjunctiva is more inflamed than the bulbar conjunctiva, and the area surrounding the cornea (limbus) is spared. Thus, pulling down the lower lid and noting the predominant area of inflammation enables one to distinguish conjunctivitis from keratitis, uveitis, and other causes of red eye.[1,4] Conjunctival hyperemia associated with Kawasaki disease or bacterial toxin-mediated syndrome is distinguished by predominant involvement of bulbar conjunctivae and lack of exudate. The concurrent presence of a serous or purulent discharge confirms the diagnosis of conjunctivitis. Scant amounts of conjunctival discharge are best confirmed by asking the patient about the presence of eyelid crusting on awakening because dried exudate accumulates along the lid margins during sleep.

Acute Conjunctivitis

Etiologies

Bacteria and viruses cause acute conjunctivitis. An epidemiologic study of 99 children with conjunctivitis published in 1981 observed that 65% of cases of acute conjunctivitis were caused by bacteria and 20% of cases by a virus.[2] A similar study of 95 children published in 1993 confirmed that the majority (78%) of infections were caused by bacteria.[3] Differentiating features of bacterial conjunctivitis and viral conjunctivitis are shown in Table 81.1.

TABLE 81.1

Clinical Findings in Acute Bacterial and Viral Conjunctivitis

Clinical Finding	Bacterial Disease	Viral Disease
Bilateral disease at onset	50%–74%	35%
Conjunctival response[a]	Papillary[b] or nonspecific	Follicular[c]
Conjunctival discharge	Mucopurulent	Watery
Conjunctival membrane	Late onset	Early onset
Preauricular adenopathy	No[d]	Yes
Concurrent otitis media	20%–73%	10%

[a] Conjunctival response refers to conjunctival appearance on slit-lamp examination.

[b] Papillary response denotes focal area of inflamed conjunctiva centered on a blood vessel.

[c] Follicular response represents focal accumulation of lymphocytes encircled by blood vessels.

[d] Except granulomatous bacterial infection.

Data from Gigliotti F, Williams WT, Hayden FG, et al. Etiology of acute conjunctivitis in children. J Pediatr 1981;98:531–536; and Weiss A, Brinser JH, Nazar-Stewart V. Acute conjunctivitis in childhood. J Pediatr 1993;122:10–14.

Bacterial Causes

Haemophilus influenzae and *Streptococcus pneumoniae*.

Nontypable *Haemophilus influenza*, *Streptococcus pneumoniae*, and *Moraxella catarrhalis* are most commonly isolated bacteria.[2,3] Collectively, these organisms are responsible for 55% to 72% of acute bacterial infections of the conjunctivae.[5] An outbreak of 698 cases of acute conjunctivitis on a college campus in 2002 was caused by an atypical, unencapsulated strain of *S. pneumoniae* that was identical to strains that had caused outbreaks two decades previously.[6]

Staphylococci.

Staphylococcus aureus and *S. epidermidis* often are recovered from “eye” cultures but are infrequently a cause of acute conjunctivitis.[3] Studies in which the lids and conjunctivae are sampled separately show that staphylococci can be recovered in relatively large numbers from lids, whereas few organisms are recovered from conjunctivae. Although staphylococci commonly colonize the lids without causing disease, they can cause blepharoconjunctivitis, a chronic infection of the lid margins.

Gram-Negative Bacilli.

Gram-negative bacilli other than *H. influenzae* occasionally cause conjunctivitis. Special clinical circumstances usually are pertinent, such as (1) exposure to broad-spectrum antibiotics that promote the emergence of gram-negative flora; (2) circumstances of poor hygiene in which children rub their eyes with fingers contaminated by feces or urine; and (3) prolonged hospitalization, especially in intensive care settings, where immobilization, exposure keratitis, and dragging of a tracheal suction catheter across the face raise the risk for direct inoculation.[7]

Neisseria gonorrhoeae.

Neisseria gonorrhoeae rarely causes conjunctivitis but is important to consider because infection can lead to corneal ulceration and blindness.[8,9] The organism binds avidly to surface receptors on the conjunctivae and cornea, triggering the release of bacterial toxins and inflammatory enzymes that damage the corneal epithelium and underlying collagenous stroma. Clinical hallmarks of infection are the onset of purulent conjunctivitis after an incubation period of less than 7 days and the presence of corneal opacification. Unusual cases of infection after incubation periods of up to 19 days and infection associated with minimal symptoms have been reported.[10,11] Beyond the neonatal period, gonococcal conjunctivitis is a result of sexual activity or abuse.[12] *N. gonorrhoeae* can be isolated from the pharynx, rectum, or genital mucosa as well as conjunctivae.

Neisseria meningitidis.

Neisseria meningitidis, a rare cause of conjunctivitis, is important because it can be complicated by meningococcemia and meningitis.[13–16] In a report of 21 cases and a review of 63 previously reported cases, Barquet and colleagues[15] noted that 18% of patients with conjunctivitis due to *N. meningitidis* experienced meningococcemia. Systemic infection was more common among those treated with topical antibiotics alone. Bilateral hyperacute conjunctivitis is typical. Conjunctival scrapings show the presence of gram-negative intracellular diplococci.

Haemophilus aegyptius.

Haemophilus aegyptius deserves special mention because it can cause a meningococcal-like illness (see Chapter 173). In South America, this organism is the cause of Brazilian purpuric fever.[17,18] Especially prominent in children younger than 10 years, this catastrophic illness typically begins as hyperacute conjunctivitis, which is followed by fever within 3 to 5 days. Disseminated purpura, hypotensive shock, and death ensue within 48 hours. Molecular studies show that all isolates causing Brazilian purpura fever are related genetically.[19] Initially, all reported cases came from São Paulo, Brazil, and the neighboring state of Parana, but new strains emerged in other regions, raising concern about the disease's potential to spread worldwide.[20] The genome of pathogenic *H. aegyptius* is larger than that of nonpathogenic strains. Frequent gene exchange between bacterial species has been shown to underlie this genetic addition.[21,22] In the United States *H. influenzae* biotype *aegyptius* (a nontypable *H. influenzae*) is associated with simple acute seasonal conjunctivitis.

Viral Causes

Viral conjunctivitis has an acute onset, spreading from one eye to the other within a week, and the inflammation lasts 4 days to 2 weeks. (Fig. 81.1) Involvement of the second eye usually is less severe than the first affected eye, and this pattern helps distinguish viral from bacterial causes. Conjunctival discharge is watery, and slit-lamp examination shows follicular hyperplasia of conjunctivae. Inflammatory membranes over the conjunctival surface can develop. Lid swelling can be minimal or marked. Invasion of the corneal epithelium (punctate keratitis) is associated with pain and photophobia. Superficial keratitis usually is transient but can evolve into an immune-mediated stromal keratitis that reduces vision. Ipsilateral preauricular adenopathy is common. Acute follicular conjunctivitis can be caused by a number of viruses, with associated ocular and nonocular clinical manifestations (Table 81.2).

TABLE 81.2

Diagnostic Features of Acute Follicular Conjunctivitis

Clinical Syndrome	Etiologic Agent	Eyelid Lesions	Corneal Lesions	Nonocular Findings
Pharyngoconjunctival fever	Adenoviruses 3 and 7	None	Punctate epithelial keratitis	Fever, pharyngitis
Epidemic keratoconjunctivitis	Adenoviruses 8, 19, and 37	Lid swelling	Early: epithelial keratitis Late: subepithelial opacities	None
Herpetic keratoconjunctivitis	Herpes simplex virus	Vesicles	Punctate epithelial keratitis Dendritic keratitis	None
Acute hemorrhagic conjunctivitis	Enterovirus 70, coxsackievirus A24	None	Punctate epithelial keratitis	Neurologic sequelae Facial palsy Radiculomyelitis
Newcastle disease	Newcastle disease virus	None	Punctate epithelial keratitis	Usually occurs in poultry workers or veterinarians
Rubella, rubeola	Rubella and rubeola viruses	Skin exanthem	Punctate epithelial keratitis	Fever, diffuse exanthem, cough, rhinorrhea; occipital, postauricular adenopathy (rubella); Koplik spots (rubeola)

Modified from Dawson CR, Sheppard JD. Follicular conjunctivitis. In: Tasman W, Jaeger EA (eds). Duane's Clinical Ophthalmology, vol 4. Philadelphia, Lippincott-Raven, 1991, pp. 1–26.

Adenovirus.

Pharyngoconjunctival fever is characterized by the concurrent presence of fever, pharyngitis, and conjunctivitis.[23,24] It is caused by adenovirus (serotypes 3 and 7) and usually affects children younger than 10 years. Although direct contact with airborne droplets is the usual mode of transmission, prolonged fecal excretion of the virus may be responsible for epidemics associated with swimming pools.[24]

Epidemic keratoconjunctivitis is the most common ocular infection due to adenovirus (usually serotypes 8, 19, and 37) in older children.[25,26] Unassociated with fever or pharyngitis, conjunctivitis often is associated with corneal inflammation. The epithelia of the cornea and conjunctiva share a membrane cofactor protein (CD46) that attaches to and promotes entry of adenovirus type 37.[25] Diffuse punctate lesions of epithelial keratitis evolve over 7 to 10 days into circumscribed subepithelial opacities that can impair vision and result in local discomfort for weeks to months. Resolution occurs without scarring. In young children, adenovirus conjunctivitis often causes ocular adnexal inflammation, eyelid edema, and erythema simulating periorbital cellulitis; an inflammatory pseudomembranous or palpebral conjunctivitis is distinctive.[27] Direct contact with infected individuals is the usual mode of transmission,[28,29] but indirect spread by common-use instruments, particularly those used by ophthalmologists, also can occur.[30,31] Adenoviral conjunctivitis can be associated with an acute respiratory infection. Faden and colleagues reported an outbreak of adenovirus 30 disease in a neonatal nursery in which 6 infants with preexisting respiratory disease expired, and ophthalmologic procedures were the infectious source.[32,33]

Herpes Simplex Virus.

Both primary and recurrent herpes simplex virus (HSV) infections can result in unilateral follicular conjunctivitis or blepharoconjunctivitis.[26] Single or multiple clusters of vesicles characteristically appear on the eyelid and progress through pustular and crusted stages before healing (Fig. 81.2). When present, accompanying corneal ulcers manifest as marginal infiltrates, punctate epithelial defects, or classic dendrites. Whenever a child or adult has had an episode of herpetic blepharoconjunctivitis, it is imperative that subsequent episodes of conjunctivitis be promptly evaluated by an ophthalmologist because recurrent episodes usually involve the cornea. Prompt antiviral treatment of herpetic keratoconjunctivitis can prevent blindness resulting from corneal scarring.

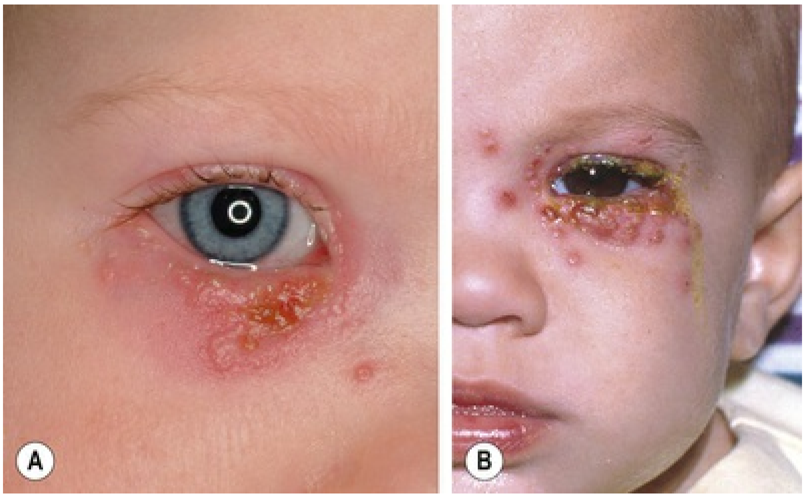

FIGURE 81.2 (A, B) Typical herpetic skin lesions of the eyelids associated with conjunctivitis in various stages of development and healing. (Courtesy of J. H. Brien ©.)

Picornaviruses.

Acute hemorrhagic conjunctivitis is a highly contagious illness usually caused by the picornaviruses, especially enterovirus 70 and coxsackievirus A24. Infection is characterized by the sudden onset of bilateral conjunctivitis associated with profuse watery discharge, lid edema, and fine, punctate epithelial keratitis.[34–36] A prominent distinguishing feature is the presence of subconjunctival hemorrhage, which can be pinpoint or confluent. The disease lasts for 3 to 5 days and resolves without adverse ocular sequelae. However, this pandemic infection can be accompanied by neurologic involvement, in particular radiculomyelitis with extremity weakness, unilateral facial nerve palsy, or other cranial neuropathies.[37,38]

Conjunctivitis-Otitis Syndrome

Because 20% to 73% of children with conjunctivitis have otitis media, children presenting with conjunctivitis should have otoscopic examinations. Nontypable *H. influenzae* is the major pathogen implicated.[39–42] In one study from France, 16% of children with acute otitis media had concurrent conjunctivitis; conjunctival exudates yielded growth of nontypable *H. influenzae* in 89% of 419 cases.[42]

Diagnosis

Most cases of acute conjunctivitis occurring in children do not require confirmation of bacterial cause because empiric therapy is cost-effective and efficacious. Conjunctival swabs should be obtained for microbiologic evaluation from affected neonates, immunocompromised children, hospitalized children, and those in whom infection caused by HSV is suspected. Etiologic agent usually cannot be predicted clinically. Bacterial cultures are more useful than viral cultures because their diagnostic yield is higher and their costs are lower. The combination of sterile culture of conjunctiva and low density of organisms from lid cultures is strong indirect evidence of a viral infection.[3] Molecular detection of adenovirus with real-time, polymerase chain reaction assay is rapid and is an acceptable alternative to viral cultures.[43,44] When HSV is a diagnostic consideration, viral cultures should be performed.

Although rarely necessary, conjunctival scraping can be helpful.[3,45] Specimens should include conjunctival epithelial cells to allow detection of intracellular pathogens. The conjunctival surface is scraped gently with a spatula after the instillation of topical anesthetic drops; swabbing of surface exudate with a cotton-tipped applicator is more likely to yield an amorphous mixture of fibrin and cellular debris than intact cells. Gram stain of the scraping provides preliminary information about the presence and relative quantity of bacteria. Giemsa stain can help to differentiate bacterial infections from viral infections; predominance of neutrophils typically is present in bacterial infections, and a predominance of lymphocytes suggests viral infection.

Treatment

Bacterial Disease

Acute conjunctivitis usually is self-limited. Topical antibiotic treatment is recommended because it speeds eradication of the offending pathogen and shortens the duration of symptoms.[46] Clinical factors for low risk for bacterial conjunctivitis, such as lack of discharge causing eyelid closure, age >6 years, and occurrence from April through November, are commonly associated with negative bacterial culture, reducing the value of treatment with antibiotics.[47,48] In general, treatment is empiric because cultures and cytologic examinations are not performed routinely. When the decision to treat with antibiotics is made, topical antibiotic therapy should be broad spectrum, nontoxic, and inexpensive.[49,50]

For infants, erythromycin ointment or polymyxin B–bacitracin ophthalmic ointment instilled 3 times a day for 5 to 7 days is well tolerated and treats most pathogens.[4,46] Ointments and solutions containing neomycin should be avoided because there is a high incidence of allergic sensitization with these agents. For older children, ophthalmic solutions should be used, and polymyxin B –trimethoprim solution or sodium sulfacetamide 5% solution are good choices for broad-spectrum coverage.[51–53] Tobramycin 3% solution is used commonly, but resistance of *Streptococcus* spp. limits effectiveness. Topical fluoroquinolones such as ciprofloxacin, ofloxacin, and norfloxacin are effective but expensive. The widespread use of topical fluoroquinolones has led to the emergence of resistant organisms; therefore their use should be restricted to infections involving the cornea or to those caused by gram-negative organisms in hospitalized patients.[54–63] Azithromycin 1.5% ophthalmic solution is well tolerated and has good coverage, especially against *Haemophilus* and many *Streptococcus* spp.[64]

Systemic antibiotics are effective in the treatment of bacterial conjunctivitis. Their use is recommended when there is concurrent acute otitis media (AOM) or streptococcal pharyngitis. Oral therapy may prevent the development of AOM. In one study, 11 of 42 (26%) patients treated with topical antibiotics alone, but only 2 of 41 (5%) patients treated with topical and systemic antibiotics, had evidence of AOM at a 2-week follow-up visit.[40] In another study, however, oral cefixime was no more effective than topical polymyxin B –bacitracin for either the eradication of conjunctival colonization or prevention of AOM.[4]

Intravenous antibiotics attain levels in the conjunctiva that are sufficient to eradicate potential pathogens. Efficacy of oral therapy is less clear because the conjunctival concentrations of drugs are substantially lower. In one study, 46 of 48 (96%) children with acute conjunctivitis treated with oral antibiotics alone had negative bacterial cultures after 3 to 5 days of therapy.[65] A controlled study by Isenberg and associates[66] indicated that topical solution of 1.25% povidone-iodine is as effective as neomycin–polymyxin B

−gramicidin in the treatment of acute conjunctivitis. Low cost and lack of microbial resistance make this an attractive option, especially in developing countries.

Herpes Simplex Virus

Treatment of HSV eye infections should be undertaken in collaboration with an ophthalmologist. Orally administered acyclovir and topical trifluridine are both effective, but intravenous therapy should be used when treating a patient with a history of atopy, a child with disseminated disease, an immunocompromised child, or a neonate.[67] Topical corticosteroid agents are contraindicated in suspected conjunctivitis and superficial keratitis due to HSV but are used by ophthalmologists on occasion, in conjunction with antiviral agents, for immune-mediated disease of the corneal stroma.

Adenovirus and Other Viruses

Treatment is supportive and may include cool compresses, use of artificial tears, and topical vasoconstrictors. Topical ketorolac 0.5%, a nonsteroidal anti-inflammatory agent, used 4 times daily is no better than artificial tears.[68] Topical cidofovir, a broad-spectrum antiviral agent, is not effective at 0.2% concentration, and the 1% concentration is limited by local toxicity.[69,70] Corticosteroid drops are contraindicated because they predispose to corneal involvement and can prolong viral shedding, as observed in an animal model.[71]

Chronic Conjunctivitis

Nasolacrimal Duct Obstruction

Nasolacrimal duct obstruction is the most common cause of chronic or recurrent eye infection of infants.[72] Although usually a developmental anomaly, sometimes obstruction can be acquired (as following local adenovirus or bacterial infection). Persistence of an imperforate membrane along the nasolacrimal duct blocks tear drainage and predisposes to secondary infection of retained tears. Consequently, tears pool in the conjunctival cul-de-sac and then spill over the lid margins, flowing onto the cheek (epiphora). At night or during sleep, spillage of infected material leads to accumulation of crusted exudate along the lid margins.

Digital compression of the lacrimal sac region usually elicits reflux of mucopurulent discharge. When reflux cannot be elicited, delayed clearance of 5% fluorescein dye instilled onto the eye confirms the diagnosis of a blocked tear duct. The conjunctiva appears normal or only minimally inflamed. The lower eyelid skin frequently becomes red and inflamed due to chronic wetness and rubbing, but the tissue is not edematous, painful, or tender, differentiating this condition from cellulitis. Topical antibiotics and digital massage of the lacrimal sac are the initial treatments of choice. Because 95% of obstructions resolve by 12 months of age, lacrimal duct probing is reserved for patients in whom obstruction persists beyond this age.

Blepharitis

Blepharitis is a primary infection of the eyelid with secondary inflammation of the conjunctiva. Blepharitis is the most common cause of chronic conjunctivitis in older children.[72,73] *S. aureus* or coagulase-negative staphylococci (CoNS) is the usual pathogen. Affected children come to medical attention because of red eyes, ocular irritation, chronic eye rubbing, and pulling of the eyelashes. Photophobia raises suspicion of corneal involvement.

Clinically, it is useful to separate blepharitis into anterior and posterior types. Anterior blepharitis is accompanied by crusting along the lid margin because of the buildup of epithelial debris and fibrin centered on the eyelashes (cilial collarettes). Close inspection reveals superficial excoriations of the lid margin and telangiectatic vessels. Chronic rubbing of the eyelid and eyelash pulling lead to breakage and partial loss of eyelashes. In posterior blepharitis, the meibomian gland orifices, located along the posterior lid margin, are blocked, causing retention of sebum and predisposing to meibomian cysts, chalazion, and secondary infections. The incidence of meibomitis peaks in young children[74] and during adolescence, when the sebaceous glands undergo hormonal stimulation. Examination reveals inspissation of meibomian glands, from which exudative material can be expressed by gentle compression of the lids with cotton applicators. Although blepharitis is a clinical diagnosis, the recovery of relatively more staphylococcal species from lid cultures than conjunctival cultures and cytologic evidence of neutrophils on Giemsa stains of conjunctival scrapings help to confirm the diagnosis.

The most common complication of blepharitis is chalazion formation. This results from obstruction of the meibomian gland orifices by debris and secondary infection. Blepharitis should be suspected in any child who demonstrates recurrent or multiple chalazions. Toxic epithelial changes of the cornea (punctate keratitis), immune-mediated subepithelial infiltrates, and marginal ulcerations can result from corneal contamination with exotoxins of staphylococci. Chronic staphylococcal keratitis can lead to corneal neovascularization and visual loss.

Blepharitis cannot be cured, but symptoms can be controlled through the use of eyelid hygiene and topical antibiotics. Lid hygiene entails applying a washcloth presoaked in warm water at least 2 to 4 times a day and scrubbing the lid margin with a cotton-tipped applicator presoaked in a 50 : 50 mixture of a nonirritating shampoo (or soap) and water. Attention to personal hygiene and avoidance of chronic eyelid rubbing are helpful in preventing contamination of the lids. Topical antibiotics should be used to treat secondary infection. Bacitracin or erythromycin ointments are appropriate choices. They should be applied 1 to 4 times daily for 1 to 2 weeks and then once daily for 4 to 8 weeks. Treatment is continued for 1 month after all signs of inflammation abate. Topical corticosteroids sometimes are required to suppress the inflammatory component but should be used only with the supervision of an ophthalmologist. Indiscriminate use of corticosteroids could lead to glaucoma and exacerbation of unrecognized herpetic eye disease. Systemic erythromycin in children younger than 8 years and systemic tetracycline in older children are effective treatment options in severe cases of blepharoconjunctivitis.[74,75] Erythromycin and tetracycline appear to accumulate in the meibomian glands, where they inhibit bacterial protein synthesis and lipase breakdown of sebum.

Chlamydial Infections

Trachoma

Trachoma is the most important ocular infection worldwide because it is a major, preventable cause of blindness.[76] *Chlamydia trachomatis*, usually serotype A, B, or C, is the usual cause of infection. Trachoma has an insidious onset in infants and young children, in whom the organism attaches to and invades the conjunctival and corneal epithelium, eliciting the formation of lymphoid follicles. Chronic inflammation causes a loss of conjunctival goblet cells with resulting mucin deficiency and subconjunctival fibrosis (particularly of the upper lid). As lymphoid follicles of the limbus regress, semilunar areas of thinned cornea, known as *Herbert pits*, appear and are pathognomonic of the disease. Progressive cicatrization of the conjunctiva can pull the lid margin inward, causing the eyelashes to rub on the cornea (trichiasis). The combined effects of chronic inflammation, mucin deficiency, and trichiasis can lead to corneal scarring, neovascularization, and blindness.

Trachoma is treated with topical erythromycin or tetracycline or with sulfacetamide ointment applied either twice daily for 2 months or twice daily for the first 5 days of the month for 6 months. Oral erythromycin or tetracycline therapy for 40 days is given if infection is severe. Single-dose azithromycin (20 mg/kg) also is effective and can be beneficial, especially in hyperendemic areas.[77–81] In one large study, the prevalence of infection fell from 9.5% before introduction of single-dose azithromycin therapy to 0.8% 24 months after introduction.[81] On the basis of a chlamydial recurrence rate of 11% at 6 months, one study proposed that repeat single-dose treatment biannually potentially could eliminate ocular *C. trachomatis*.[82]

Inclusion Conjunctivitis of the Adolescent

C. trachomatis (serotypes D through K) is the most common sexually transmitted infection, with disproportionate occurrence in sexually active adolescents.[83,84] The clinical hallmark of eye involvement is a unilateral follicular conjunctivitis with mucopurulent discharge, eyelid swelling, and ipsilateral preauricular adenopathy. Photophobia and severe irritation are symptoms consistent with corneal involvement. The organism invades the corneal epithelium, resulting in a superficial keratitis that can progress to subepithelial infiltrates and micropannus formation. If untreated, the disease can persist for months to years. Diagnosis is based on positive cultures, detection of chlamydial antigens, or molecular techniques. Treatment consists of systemic tetracycline, doxycycline, or erythromycin for 7 days or longer; or azithromycin in a single 1-g oral dose likely also would be effective.

Parinaud Oculoglandular Syndrome

Parinaud oculoglandular conjunctivitis is a syndrome characterized by the presence of granulomatous conjunctivitis and ipsilateral preauricular or submandibular adenopathy. Usually unilateral, there may be one or more granulomas of the upper or lower palpebral conjunctiva. Fever, malaise, and other systemic signs can be present. *Bartonella henselae* is the most common cause,[85] but oculoglandular syndrome also can be associated with tularemia, sporotrichosis, tuberculosis, syphilis, and infectious mononucleosis.

Viruses

Viruses rarely cause chronic conjunctivitis, with the exception of molluscum contagiosum, a poxvirus infection. One or more umbilicated papules of varying size on the eyelid is the cardinal feature. Rupture of lesions on the eyelid margin releases molluscum bodies onto the conjunctiva, inciting a follicular response.[86] Molluscum contagiosum of the eyelids can be a manifestation of human immunodeficiency virus infection.[87] Diagnosis is based on the presence of typical lesions on the lid and elsewhere on the skin. Treatment consists of excision, curettage, or cryopexy of individual lesions.[88]

Allergic Conjunctivitis

Children with allergic conjunctivitis can come to attention acutely, with sudden onset of conjunctival edema and redness, itching, and watery discharge, or can manifest chronic itchy red eyes with minimal discharge. Symptoms often are seasonal and may be accompanied by other signs of seasonal allergies such as nasal congestion and rhinorrhea, cough, and generalized pruritus. Children with atopy are particularly prone to developing allergic conjunctivitis. Treatment includes minimizing exposure to offending allergens, use of artificial tears, topical administration of antihistamine or mast cell stabilizers, or use of systemic antihistamines. Occasionally, topical corticosteroids are required to control severe disease.[89]

Key Points

Pediatric Conjunctivitis

Epidemiology

- Common condition in children
- Usually self limited; exceptions when etiology is *Neisseria gonorrhoeae*, *Chlamydia trachomatis,* or herpes simplex virus

Clinical Features

- Allergic: red eyes; itchy, watery discharge with accompanying signs and symptoms of seasonal allergies (e.g., rhinorrhea, sneezing, urticaria)
- Viral: red eyes; itchy, watery discharge with accompanying signs of upper respiratory infection; sick contact; preauricular adenopathy if adenovirus; second eye less affected than first
- Bacterial: mucopurulent discharge, often unilateral, sometimes with accompanying acute otitis media
- Herpetic: foreign body sensation, follicular conjunctivitis, watery discharge; occurs more commonly in atopic children

Diagnosis

- Usually a clinical diagnosis

- If hyperpurulent or possibility of sexually transmitted infection, obtain bacterial culture and susceptibility testing, *Chlamydia* culture, nucleic acid amplification test, or immunofluorescent testing.

- If accompanying keratitis, obtain bacterial culture and susceptibility testing and obtain polymerase chain reaction for herpes simplex.

Treatment

- Allergic: avoid allergen; use artificial tears, topical antihistamine, topical mast cell stabilizer, oral antihistamine

- Viral: most cases self-limited and require only symptomatic relief, artificial tears, topical nonsteroidal agent; highly contagious

- Bacterial: broad-spectrum antibiotic polymyxin B−trimethoprim solution speeds resolution of symptoms

- Herpetic: if corneal involvement, use systemic acyclovir; topical agents also are effective but can cause local irritation

Infective Keratitis

Douglas R. Fredrick

Infective keratitis is an uncommon but important infection because it has the potential to cause blindness. It can be caused by a wide variety of microorganisms. Most children with corneal infections come to medical attention because of a painful red eye. Distinguishing infectious keratitis from other causes of red eye accurately and promptly is extremely important.

Pathogenesis

The cornea is susceptible to microbial invasion because of its exposed position, avascularity, and limited inflammatory repertoire. Apart from epithelial Langerhans cells, the normal cornea lacks white cells, which must be recruited from the tear film, limbal lymphoid aggregates, and perilimbal circulation.[1,2] The epithelium and its basement membrane serve as a relative barrier to most infectious agents, but, once breached, the hypocellular stroma is vulnerable to infection, often with organisms of low virulence. Release of proteases, collagenases, and oxygen-derived free radicals from invasive organisms and infiltrating neutrophils degrades collagen and proteoglycans, the major constituents of the corneal stroma.

Trauma caused by the use of contact lenses is the most common factor predisposing to bacterial and fungal keratitis in children (Box 82.1).[3–7] Trauma from contact lenses can cause epithelial damage and corneal hypoxia. The risk for bacterial keratitis is 10- to 15-fold greater in subjects who wear contact lenses overnight compared with users of daily-wear lenses.[8] Orthokeratology, a procedure for reshaping the cornea by wearing nocturnal contact lenses, is popular among teenagers and predisposes to corneal infections.[9] Dry eyes, related to a deficient tear film or abnormality of the ocular surface, corneal anesthesia, and prior treatment with topical corticosteroid agents are other factors increasing the risk for bacterial keratitis. In developing countries, malnutrition, vitamin A deficiency, poor hygiene, and trachoma also predispose to corneal infections.[10]

Box 82.1

Risk Factors for Bacterial Keratitis in Children

Trauma

Corneal foreign body

Corneal abrasion or laceration

Contact lens wear

Trichiasis or distichiasis

Prior ocular or eyelid surgery

Corneal Exposure

Congenital and acquired disorders of the eyelids

Globe proptosis

Facial palsy

Moribund or sedated state

Abnormalities of the Ocular Surface

Dry-eye syndrome

Mucin deficiency from loss of goblet cells

Malnutrition

Corneal anesthesia

Ocular rosacea

Immunodeficiency States

Topical corticosteroid therapy

Immunosuppressive therapy

Immune deficiency syndrome

Atopy

Inadequate eyelid closure is another risk factor for infective keratitis. Corneal exposure in the severely ill or sedated child predisposes to breakdown of the epithelium and secondary infection.[3] Children with eyelid defects, facial nerve weakness, and proptotic globes, as well as those in intensive care under pharmacologic paralysis, are prone to exposure keratopathy and secondary infection. Protocols must be in place to ensure eyelid closure and lubrication in these patients.[11] Premature infants and older children receiving mechanical ventilators are particularly susceptible to conjunctival colonization with *Pseudomonas aeruginosa* and keratitis.[12–14]

Clinical Presentation

Severe pain is the hallmark of infective keratitis. Reflex tearing, redness of the eye, photophobia, and decreased vision are prominent symptoms. Keratitis usually is distinguished by the presence of greyish corneal opacification. Loss of the epithelium over the corneal infiltrate dulls the corneal light reflex and permits topically applied fluorescein dye to stain the area. Progressive destruction can lead to corneal thinning and eventual perforation. The anterior chamber can contain dispersed inflammatory cells or visible aggregates of neutrophils layering inferiorly (hypopyon). In an uncooperative child, examination of the eye is facilitated by the use of a topical anesthetic and a lid speculum.

Etiology

Herpes Simplex Virus

Keratoconjunctivitis caused by herpes simplex virus (HSV) usually is mild and, during the primary episode of infection, is indistinguishable from other causes of viral conjunctivitis except by the presence of skin or corneal lesions. The most common manifestations are unilateral follicular conjunctivitis, watery ocular discharge, and preauricular adenopathy.[15] Inspection of the swollen lids often reveals the presence of vesicles or lid margin ulcerations. Initially, the cornea is spared, but within a few days to 2 weeks, mild punctate keratitis or dendritic keratitis develops in about one half of infected children (Fig. 82.1). Primary herpetic keratitis is self-limited in most children beyond the neonatal period.

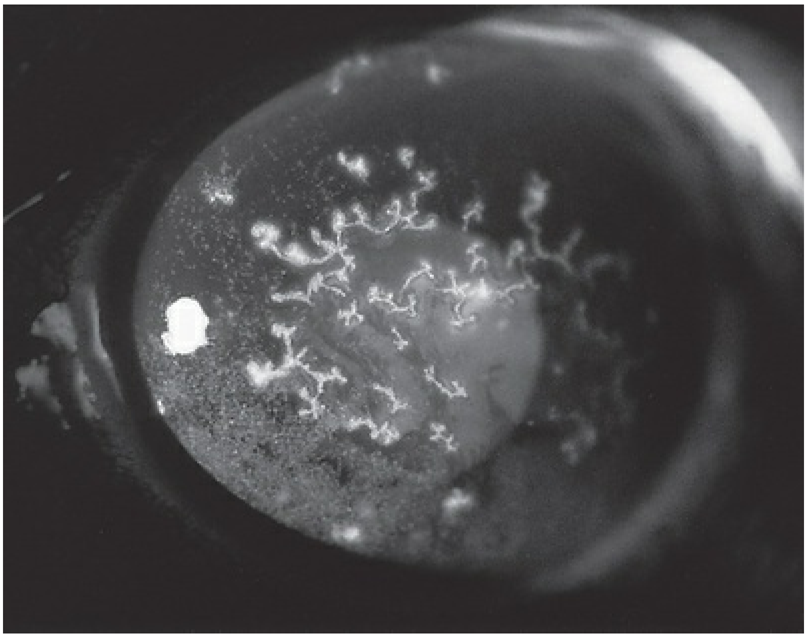

FIGURE 82.1 Classic appearance of primary herpes simplex virus keratitis stained with 1% fluorescein, showing multiple epithelial dendrites.

Most episodes of herpetic keratitis represent recurrent disease after primary infection that has resulted in latent infection of the cornea or trigeminal ganglion. Most recurrent episodes are not accompanied by vesicular skin lesions, but rather manifest as red eye, photophobia, watery discharge, and blurred vision. Up to 38% of children will develop recurrence during childhood. The number, frequency, and type of recurrences are highly variable, with worse vision developing in children who have multiple recurrences.[15–17] The spectrum of recurrent HSV keratitis includes epithelial dendrites (Fig. 82.2), large geographic defects, immune-mediated diskiform edema (Fig. 82.3), necrotizing keratitis complicated by corneal thinning or perforation, and chronic neurotrophic ulcerations. There are few serious sequelae if infection remains confined to the corneal epithelium, but if stromal disease ensues, progressive corneal scarring can result in permanent visual loss.

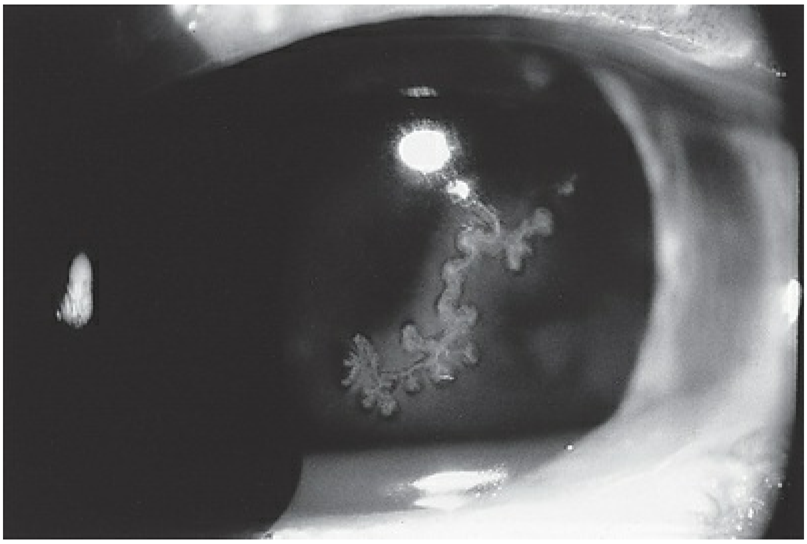

FIGURE 82.2 Slit-lamp appearance of recurrent dendritic keratitis due to herpes simplex virus stained with 1% fluorescein.

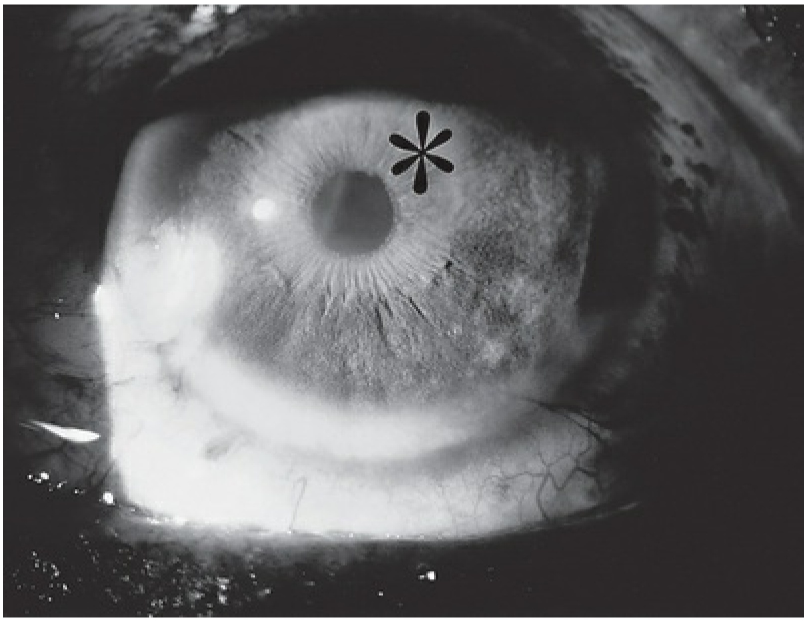

FIGURE 82.3 Herpes simplex virus diskiform keratitis, consisting of a disk-like area of stromal edema *(asterisk)* believed to be a cell-mediated immune response to residual herpes simplex virus antigen.

Varicella-Zoster Virus

Infection caused by varicella-zoster virus (VZV) can be associated with small vesicular or papular eruptions at the limbus. These lesions usually resolve without sequelae, but the affected conjunctiva often is red and painful. Less frequent corneal manifestations of VZV infection include superficial punctate epithelial defects, linear dendrites, and diskiform or necrotizing keratitis with ulceration. Recurrent epithelial or stromal keratitis also occurs.[16,18]

Herpes zoster ophthalmicus refers to reactivation of VZV along the sensory distribution of the ophthalmic division of the trigeminal nerve. Although uncommon in childhood, it can occur because of immunosuppression or after infection contracted during the first year of life.[19] A vesicular eruption is confined to the branches of the ophthalmic nerve. Uveitis and keratitis are the most common ocular manifestations. In the acute infectious stage, examination of the cornea can reveal punctate, dendritic, or geographic epithelial inflammation, which can progress to necrotizing stromal keratitis.[14,20] An immune-mediated response to varicella-related antigens appears as a delayed-onset diskiform or nummular (coin-shaped) keratitis. A chronic and recurrent epithelial or stromal keratitis can occur.[21] All children with zoster ophthalmicus must undergo a funduscopic examination because chorioretinitis can lead to permanent visual impairment. Although herpes zoster infections in previously vaccinated children tend to be mild, some children can have severe sclerokeratitis and anterior uveitis, which can lead to increased intraocular pressure and glaucoma.[22]

Other Viruses

Measles, mumps, rubella, adenovirus, coxsackievirus A24, and enterovirus 70 are associated commonly with a self-limited punctate epithelial keratitis; however, there are important exceptions. Epithelial lesions associated with adenovirus infections sometimes progress over 10 to 14 days to subepithelial opacities that can persist for months.[23] Measles keratitis usually is mild but can cause severe corneal disease when contracted by malnourished, immunocompromised, or vitamin A−deficient children.[24,25] Localized edema of the corneal stroma can, on occasion, be a delayed complication of mumps.[26]

Epstein-Barr virus can invade all layers of the cornea. Superficially there can be multiple epithelial dendrites. Stromal disease is more common and is characterized by multiple coin-shaped lesions in the anterior and mid stroma or recurrent infiltrate of the deeper layers associated with vascularization.[27–29] The condition resolves spontaneously without ocular sequelae; symptomatic treatment with artificial tears is sufficient.

Bacteria

Bacterial infection of the cornea is considered a medical emergency because it can progress rapidly and lead to severe visual loss. The presence of a dense greyish infiltrate and surface ulceration in an actively inflamed eye should be considered bacterial infection until proved otherwise (Fig. 82.4). Infection can be caused by a wide range of gram-positive and gram-negative organisms.[3–6] *Staphylococcus aureus* and streptococcal species are among the most common gram-positive isolates, especially in cooler climates. *Staphylococcus epidermidis* frequently is isolated from corneal cultures, but this often represents contamination from the eyelids. *P. aeruginosa* is the most common gram-negative isolate, especially among contact lens wearers. Ulcerative keratitis also can complicate bacterial conjunctivitis due to *Haemophilus influenzae* and *Moraxella catarrhalis*. *Shigella* and other enteric pathogens can cause keratitis after transfer to the eyes by fingers contaminated from extraocular sites of infection. The most common causes of bacterial keratitis in children are staphylococci and streptococci, seen in children who have chronic bacterial blepharokeratoconjunctivitis. These children often have itchy and burning eyes, photophobia, and tearing. On examination, debris on the eyelashes ("scurf") is seen, which represents protein exudate from inflamed eyelids. Lid margins are red, the myeibomian glands are inspissated with thickened oil, telangiectasia may be seen in ocular rosacea, and there is inflammation of the conjunctiva and cornea. The cornea may have infiltrates at the lid margins, and ulceration and neovascularization can result from chronic inflammation. Chronic cases can appear clinically similar to herpetic eye disease.[30]

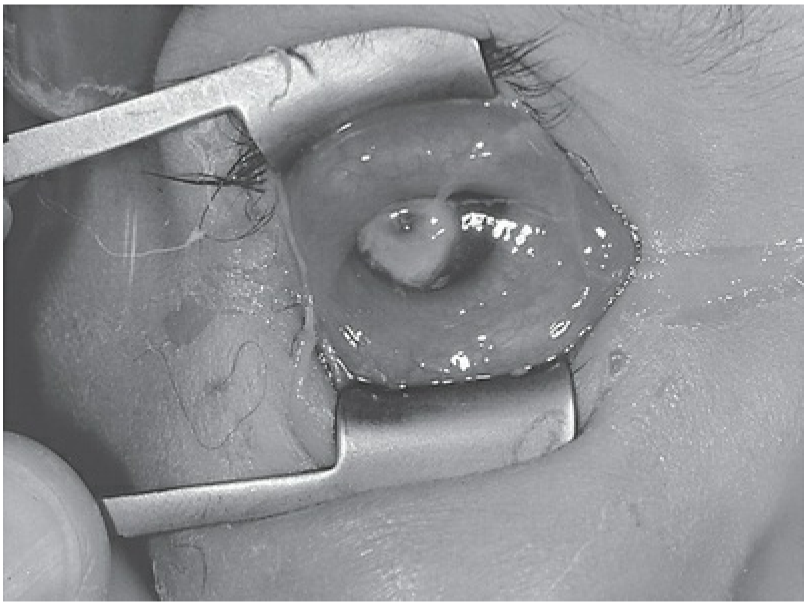

FIGURE 82.4 Perforated keratitis due to *Streptococcus pneumoniae* in a 3-year-old child after an eye injury.

Fungi

Fungal keratitis is rare in childhood and usually is the consequence of ocular trauma, especially with vegetable matter. The prior use of topical corticosteroid agents, systemic immunosuppression, preexisting corneal disease, and tropical environment increase the risk for fungal infection. *Fusarium* spp. were isolated in an outbreak of corneal ulcers associated with the use of a specific contact lens solution.[31] Typically, the ulcer has a subacute onset and progresses insidiously. Slit-lamp examination commonly reveals a yellow-white infiltrate with feathery edges; a dry, raised surface; and satellite lesions.[32,33] A wide range of fungi can be corneal pathogens. *Aspergillus* and *Fusarium* spp. are the most common pathogens worldwide.[3–6,33,34] In the United States, *F. solani* is the most common pathogen in southern states, whereas *Aspergillus* spp. and *Candida albicans* are most common elsewhere.[35,36] Dematiaceous (pigmented) fungi, particularly *Curvularia* spp., are emerging as important corneal pathogens.[33]

Acanthamoeba Keratitis

Acanthamoeba causes a recalcitrant keratitis that frequently leads to visual loss. It usually occurs in contact lens wearers or in persons exposed to contaminated water.[37,38] Severe pain, out of proportion to the severity of the keratitis, is common. This seems to be related to a propensity of the organism to infiltrate corneal nerve endings.[39] Initially, corneal epithelium is involved, and later a stromal infiltrate develops. As the infection progresses the infiltrate becomes most dense at the periphery, giving rise to a characteristic ring-shaped lesion.[40–42]

Interstitial and Marginal Keratitis

Interstitial keratitis usually is a delayed manifestation of a systemic infection from a variety of bacterial, viral, and parasitic pathogens. Congenital syphilis historically was the predominant cause of interstitial keratitis.[43,44] *Mycobacterium tuberculosis,* nontuberculous mycobacteria, *Borrelia burgdorferi,* herpesviruses, and onchocerciasis now are more common causes. Interstitial keratitis represents an immune-mediated reaction to retained microbial antigens rather than active infection. Pain, photophobia, and reflex tearing are the major symptoms. Examination reveals an intact corneal epithelium with underlying cellular infiltration of the superficial or deep stroma. Limbal blood vessels often proliferate and extend into the opacities. After the inflammation subsides, the opacities and blood vessels regress, leaving stromal scars and ghost vessels. Depending on the severity of scarring, final visual acuity ranges from 20/20 to 20/200.[45]

Staphylococcal lid disease is associated with a marginal keratitis in which infiltrates form in the peripheral cornea, often where the lid margins cross the limbus (at 2, 4, 8, and 10 o'clock). Cultures of the infiltrates are sterile, suggesting that they result from hypersensitivity reactions to staphylococcal antigens or exotoxins deposited on the ocular surface (Fig. 82.5). Ocular rosacea can lead to corneal ulceration and should be considered in patients with eyelid disease and recurrent keratitis.[46]

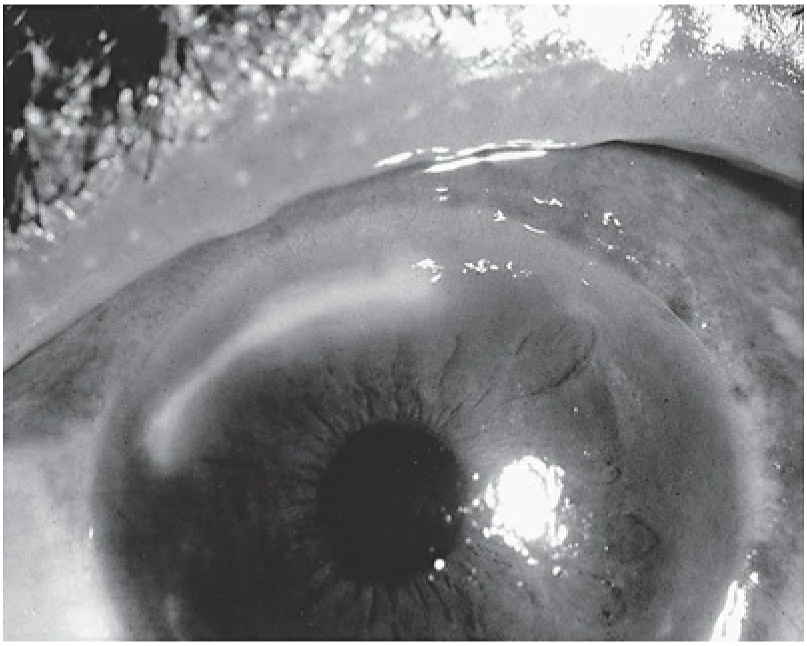

FIGURE 82.5 Extensive marginal keratitis in a child secondary to staphylococcal lid disease. Note the characteristic lucid interval between arcuate infiltrate and corneal limbus.

Diagnostic Procedures

Evaluation of infectious keratitis should include corneal scrapings for smears and cultures. Children often require sedation or examination under anesthesia to allow thorough evaluation and collection of appropriate specimens. Corneal specimens are obtained by scraping the leading edge and base of the ulcer with a sterilized Kimura spatula or Calgi swab.[47,48] Specimens from the lids and conjunctiva should be collected and cultured separately. Ideally, specimens should be inoculated directly onto the culture media because corneal scrapings contain small numbers of fastidious organisms. Amies transport media without charcoal is a useful alternative in the clinical setting.[49] Culture media should include blood and chocolate agar, anaerobic blood agar, Sabouraud dextrose agar (without cycloheximide), and enriched thioglycolate broth. *Acanthamoeba* spp. can be isolated using nonnutrient agar plates overlaid with a dried broth culture of *Escherichia coli.*

Staining of corneal scrapings is important for the early identification of bacteria, fungi, and *Acanthamoeba* and may provide the sole etiologic evidence in culture-negative cases.[47,48] Multiple specimens should be taken for Gram, Giemsa, and other specialized stains. Methenamine silver, acridine orange, and Calcofluor white stains are useful for the detection of fungi and *Acanthamoeba.*[50,51]

Microbial antigens can be detected using immunodiagnostic methods. Enzyme immunoassays and fluorescein-labeled monoclonal antibodies are especially useful in the diagnosis of chlamydial, herpetic, and other viral infections. Recombinant DNA methods have been applied to the detection of corneal fungi, herpes and other viruses, and *Acanthamoeba.*[52–54] Fungi and *Acanthamoeba* can be visualized directly in the cornea with confocal slit-lamp microscopy.[55]

Lumbar puncture should be performed in neonates with suspected herpetic eye disease. Diagnosis is done by polymerase chain reaction testing of cerebrospinal fluid and plasma for HSV.

Treatment

The mainstay of treatment for corneal infections is the intensive use of topical anti-infective agents.[56] Corneal ulcers are medical emergencies. Although some children with keratitis can be managed successfully in an outpatient setting,[57] most require inpatient care. Mydriatic drops should be used to avoid pupillary synechiae and provide comfort; ciliary spasm contributes to photophobia.

Viruses

With the exception of herpesvirus eye disease, the treatment of viral infections is symptomatic because infections are self-limited, and no effective therapy is currently available. Epithelial HSV infections can be debrided or treated with topical antiviral drugs, either vidarabine ointment (Vira-A) or trifluorothymidine (Viroptic) drops or systemic acyclovir. Drops are administered while the patient is awake every 2 hours during the first week and every 6 hours during the second week, and then rapidly tapered because these drugs are toxic to the corneal epithelium.[14] Acyclovir administered systemically is equally effective in the treatment of herpetic keratitis and represents an alternative to topical therapy.[17,58,59] Topical ganciclovir also is available and has similar efficacy to acyclovir. Children with recurrent episodes of herpetic keratitis may benefit from long-term prophylactic use of acyclovir to prevent recurrence, but resistance to acyclovir can develop over time.[60] Stromal HSV disease may require the addition of topical corticosteroid agents, but concomitant use with topical antiviral agents is necessary to prevent the reactivation of epithelial infection. Herpes zoster keratouveitis is unresponsive to available topical antiviral agents and is best managed with frequent application of corticosteroid topically and acyclovir (80 mg/kg/day) orally.

Bacteria

The mainstay of treatment for bacterial keratitis is a combination of a cephalosporin (50 mg/mL) drops and a fortified aminoglycoside, either tobramycin (15 mg/mL) or gentamicin (14 mg/mL).[45] Cefazolin is selected for gram-positive coverage, and ceftazidime is used when there is concern about *P. aeruginosa.* Toxicity, drug instability, and variability of concentration and pH of fortified antibiotics led to the use of topical fluoroquinolone antibiotics, including ciprofloxacin, ofloxacin, and norfloxacin. Several studies have shown ciprofloxacin to be an effective single agent in the treatment of bacterial keratitis.[61,62] Increasing resistance of gram-positive cocci and *Actinomyces* and *Pseudomonas* spp. to ciprofloxacin prompted the concurrent use of a cephalosporin and treatment of bacterial keratitis with a newer generation of fluoroquinolones.[63–67] Levofloxacin penetrates ocular tissues effectively and has superior gram-positive coverage; however, increasing resistance to this agent is reported.[67,68] Moxifloxacin has lower minimal inhibitory concentration (MIC) for gram-positive organisms, and gatifloxacin has lower MIC for gram-negative organisms. Both are active against methicillin-susceptible *S. aureus* isolates.[69] The newer fluoroquinolones are reported to have better in vitro activities, increased ocular penetration, and potentially lower rates of development of resistance than other fluoroquinolones.[70] Severe cases of bacterial keratitis should be treated with a cephalosporin combined with a fluoroquinolone or aminoglycoside. Choices for methicillin-resistant *S. aureus* are limited to gentamicin and vancomycin.

Because of their rapid clearance, topical antibiotics should be administered frequently, beginning with 1 drop every minute for 5 minutes, followed by doses every 15 to 30 minutes until culture results are available.[71] Subsequent therapy is modified according to culture results and clinical course, but treatment usually is continued for 7 to 14 days. A favorable therapeutic response is indicated by diminished pain, healing of the epithelium, decrease in size and density of the corneal infiltrate, and decrease in corneal edema and inflammation in the anterior chamber.

Patients with chronic staphylococcal blepharokeratoconjunctivitis require intensive eyelid hygiene, using warm compresses to liquefy inspissated material in the glands, eyelid scrubs with mild soap to remove debris, topical antibiotics such as erythromycin or bacitracin ointment to treat the bacteria, and sometimes a course of oral antibiotics.[30]

Fungi

Fungal keratitis is treated with topical natamycin, flucytosine, amphotericin B, miconazole, or flucytosine.[32,33] Frequent (hourly) initial instillation is slowly reduced over several weeks. Adequate treatment requires 6 to 12 weeks owing to poor corneal penetration and the slow growth of fungi. Lack of a therapeutic response should prompt the addition of parenteral therapy or consideration of excisional keratoplasty.[72] Deep fungal keratitis requires parenteral therapy from the outset because of the risk for fungal endophthalmitis. Subconjunctival fluconazole can be helpful in severe fungal keratitis unresponsive to topical and systemic therapy.[73]

Acanthamoeba Keratitis

Treatment of *Acanthamoeba* keratitis often is complicated by delayed diagnosis. Early and aggressive therapy with cationic disinfectants (polyhexamethylene biguanide or chlorhexidine), combined with dibrompropamidine isethionate (Brolene) and neomycin, can be curative.[74–79] Both cationic compounds result in rapid killing of the trophozoites and cysts at concentrations that are not toxic to corneal cells.[80] Clearance of *Acanthamoeba* trophozoites and cysts requires months of treatment.[81] Corneal transplantation is only recommended when the infection continues, and anti-infectives will be required long term to prevent recurrence in the graft.

Complications

Long-term complications usually are related to loss of corneal transparency and refractive changes. Central corneal scars (leukomas) that obstruct the visual axis can cause serious visual loss. Although the severity of scarring tends to diminish over time, even short periods of visual deprivation in children younger than 8 years of age can result in development of amblyopia. Although corneal transplants can restore vision,[81] corneal grafting in children may fail because of graft rejection.

Infective Uveitis, Retinitis, and Chorioretinitis

Douglas R. Fredrick

Uveitis refers to any intraocular inflammation. *Anterior uveitis* is characterized by inflammation of the iris and ciliary body (*iridocyclitis*). *Intermediate uveitis* includes inflammation of the pars plana and vitreous (*pars planitis*, *vitritis*). *Posterior uveitis* features inflammation of the retina and choroid (*retinitis*, *choroiditis*). Uveitis is an uncommon disorder in childhood; among affected children, the anterior form is more common than the posterior form.

Anterior Uveitis

Table 83.1 summarizes the important pathogens and disorders responsible for anterior uveitis, with distinguishing features of each. After Kawasaki disease, at least one half of children with an identifiable cause of anterior uveitis have juvenile idiopathic arthritis or human leukocyte antigen (HLA)-B27−related spondyloarthropathy.[1,2]

TABLE 83.1

Common Causes of Anterior Uveitis

Organism or Condition	Duration	Associated Ocular Findings	Associated Systemic Findings
Varicella	Acute	Iris atrophy (rare)	Vesicular skin rash
Herpes simplex	Acute	Keratitis	None
Mumps	Acute	NS	Fever, headache, parotitis
Influenza	Acute	NS	Febrile respiratory illness
Epstein-Barr virus mononucleosis	Acute	NS	Fever, pharyngitis, lymphadenopathy
Measles	Acute	NS	Fever, coryza, Koplik spots
Kawasaki disease	Acute	NS	Fever, mucocutaneous findings, peripheral edema, unilateral lymphadenopathy
Herpes zoster	Chronic	Iris atrophy (common), KP	Fever, vesicular skin rash
Syphilis	Chronic	Iris nodules, chorioretinitis, optic neuritis	Maculopapular skin rash (palms and soles)
Tuberculosis	Chronic	Iris nodules, granulomatous KP, choroidal granulomas	Pulmonary lesions
Lyme disease	Chronic	Keratitis, optic neuritis	Erythema migrans, arthritis
Leprosy	Chronic	"Iris pearls" of iris atropy	Peripheral neuropathy, skin lesions

KP, keratitic precipitates that represent aggregates of inflammatory cells on the corneal endothelium; NS, nonspecific.

Clinical Manifestations

Patients with anterior uveitis come to attention because of ocular pain, photophobia, and blurred vision. The whole eye looks red, but closer inspection reveals that the predominant area of hyperemia is at the corneal limbus owing to the vascular engorgement of the underlying ciliary body. Slit-lamp examination allows visualization of (1) cells floating in the anterior chamber or adherent to the corneal endothelium (keratic precipitates) and (2) turbidity of the normally optically clear aqueous humor resulting from the spillover of protein (flare). Distortion of the pupil is related to formation of inflammatory scars between the iris and lens surface (synechiae). Dystrophic calcification of the epithelial basement membrane (band keratopathy), iris nodules, lens opacities, and phthisis bulbi can occur.

Etiologies

Viruses

Many viruses are associated with an acute nongranulomatous uveitis that is mild and self-limited.[3,4] Varicella-zoster virus (VZV) demonstrates the spectrum of disease involvement. Anterior uveitis resulting in mild inflammation occurs in up to 25% of patients with chickenpox.[5,6] It tends to be self-limited, resolving within 10 to 14 days. By contrast, uveitis associated with herpes zoster ophthalmicus is more severe and usually requires aggressive treatment with a topical corticosteroid, cycloplegic agents, and systemic acyclovir. Devastating visual complications can occur when there is concurrent involvement of structures of the posterior segment. Uveitis associated with herpes simplex virus (HSV) infection usually is a complication of a deep keratitis but can occur without antecedent keratitis.[7]

Mycobacterium tuberculosis

Chronic granulomatous uveitis, sometimes in association with iris nodules, once was caused commonly by *Mycobacterium tuberculosis*.[8] It is now uncommon, except in developing countries and in patients with acquired immunodeficiency syndrome (AIDS).

Treponema pallidum

The incidence of congenital syphilis parallels the incidence of syphilis among heterosexual persons in the United States. Congenital syphilis also remains a problem in developing countries. Chorioretinitis is a classic sign of early congenital syphilis, "salt-and-pepper" pigmentary changes of the peripheral retina being the most common finding.[9,10] Although anterior uveitis is a common presentation, some patients predominantly have intense posterior uveitis with necrotizing retinitis, retinal vasculitis, or optic neuritis.[11,12]

Borrelia burgdorferi

Borrelia burgdorferi, the organism responsible for Lyme borreliosis, can invade the cornea (keratitis) and uveal tract (iridocyclitis), and infection of the vitreous retina and choroid is documented with growing frequency.[13,14] Lyme uveitis can be a late manifestation of Lyme disease.[15,16]

Kawasaki Disease

Anterior uveitis is common in Kawasaki disease. In one prospective study, anterior uveitis was found in 83% of 41 patients with Kawasaki disease in the first week of the disease.[17] Iridocyclitis and periorbital vasculitis also have been described. Conjunctival hyperemia is present in >90% of cases.

Posterior Uveitis (Retinitis)

Table 83.2 summarizes the predominant ocular manifestations and associated findings for the infectious agents most commonly implicated in retinitis.

TABLE 83.2

Common Infectious Causes of Retinitis

Organism	Predominant Manifestation	Associated Findings
Toxoplasma gondii	Necrotizing retinitis	Vitritis, optic neuritis
Rubella virus	Pigmentary retinopathy	Cataract, microphthalmia
Cytomegalovirus	Hemorrhagic retinitis	Cotton-wool spots
Herpes simplex virus	Necrotizing retinitis	Vitritis, vasculitis, optic neuritis
Varicella-zoster virus	Necrotizing retinitis	Occlusive vasculitis, vitritis
Toxocara canis	Retinal granuloma	Vitritis, endophthalmitis

Bacteria and Fungi

Before the advent of effective antibacterial and antifungal therapies, the prevalence of septic emboli and secondary retinitis from bloodstream infection (BSI) was high. The presence of Roth spots (white-centered intraretinal hemorrhages, once believed to be pathognomonic for septic emboli) was a sign of endocarditis. In fact, white-centered hemorrhages are nonspecific and can be seen with septic emboli, clotting abnormalities, trauma, vascular occlusive disease, and vasculitis.[18] The white center can be composed of a fibrin aggregate or can be a mixture of inflammatory cells, bacteria, or fungal organisms. In patients with BSI from infective endocarditis or catheter-related infection, the appearance and resolution of septic emboli can be used to monitor antibacterial therapy.

The incidence of positive retinal findings in patients with fungal BSI ranges from 7% to 20%, with a highest incidence in neutropenic patients receiving chemotherapy or after organ or bone marrow transplantation.[19–22] The incidence in children is lower than in adults.[23] In premature infants, fungal emboli to the crystalline tunica vasculosa lentis can cause inflammatory ocular disease that mimics retinopathy of prematurity, congenital cataracts, or conjunctivitis. Systemic treatment of *Candida* and other fungi with amphotericin, an echinocandin, or voriconazole usually results in resolution of chorioretinal infection; the need for intravitreal injections and surgical vitrectomy has decreased in recent years.[24] For patients with BSI whose initial examination is negative but whose BSI persists, serial examinations should be performed to make certain that there are not new lesions.[25,26]

Toxoplasma gondii

Toxoplasmosis is the most common cause of posterior uveitis in immunocompetent individuals. Infection can be contracted prenatally or postnatally[27–29]; the proportion of prenatal versus postnatally acquired retinal infections varies geographically, and the latter by host conditions. Evidence of congenital infection may be identified at birth as active retinal lesions or inactive chorioretinal scars, or may not become clinically evident until months or years later.[30,31] Acquired infections can be associated with acute or delayed onset of ocular disease. Peak occurrence of acquired infection is between the second and fourth decades of life. Active lesions appear as fluffy, white areas of focal necrotizing retinitis attributable to proliferation of live parasites and reactive inflammatory cells in the overlying vitreous.[31] In some cases, the vitreal reaction is so severe that it obscures the underlying retina, giving the so-called "headlight-in-a-fog" appearance (Fig. 83.1). Healing of these lesions leaves atrophic chorioretinal scars, which can be located in the macula or the peripheral retina (Fig. 83.2). In addition to focal retinitis, there are atypical presentations. Punctate outer retinal toxoplasmosis is characterized by the presence of grey-white lesions of the outer retina with little or no overlying vitritis. In children, an asymptomatic scar is the most common finding, but infection can manifest as uveitis, retinitis, or optic neuritis in up to 20% of cases.[32] Healed lesions appear as granular white opacities. Neuroretinitis features optic disk swelling with macular exudates and visual loss and multifocal retinal infiltrates.[33] Optic neuritis can follow infections of the nerve or surrounding retina.

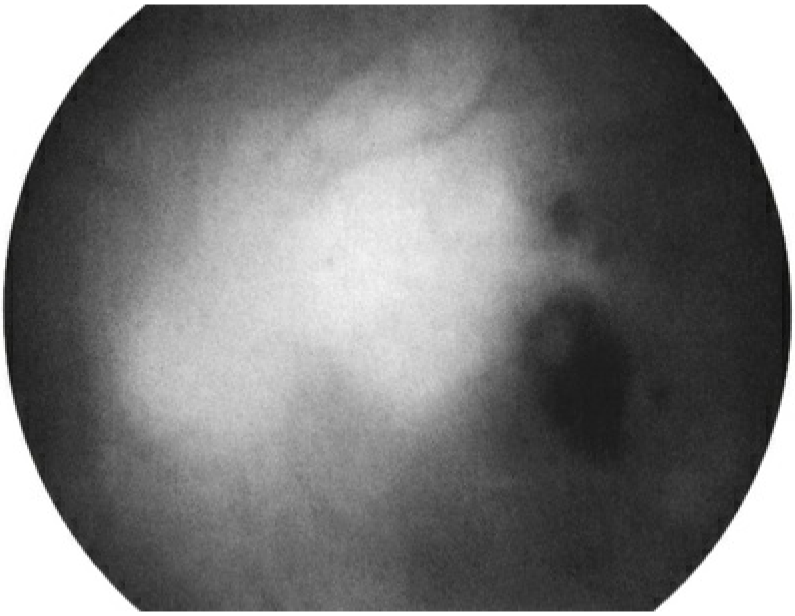

FIGURE 83.1 Fundus photograph shows an active toxoplasmic lesion situated at the edge of a pigmented chorioretinal scar; the view is hazy because there are inflammatory cells in the overlying vitreous.

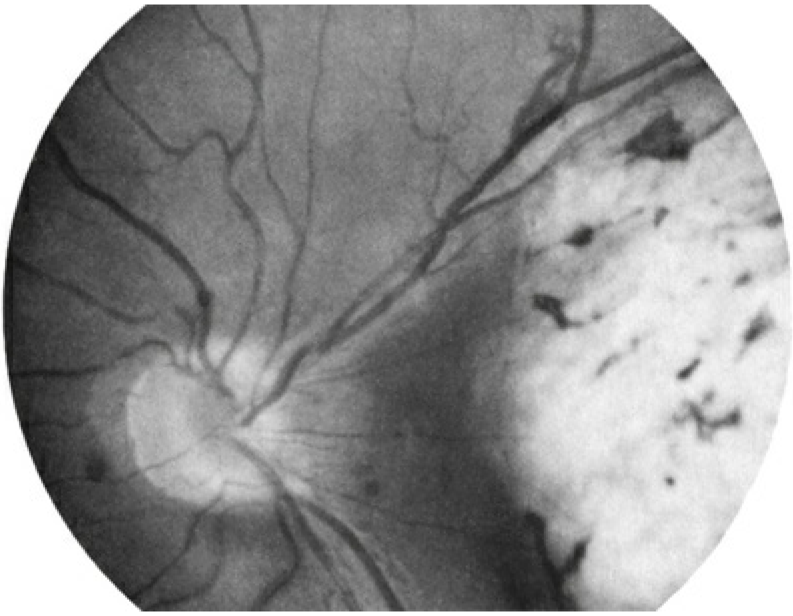

FIGURE 83.2 Fundus photograph shows a portion of a toxoplasmic chorioretinal scar centered on the macula with scattered clumping of retinal pigmentation.

Trapping of protozoa within the terminal branches of abundant perifoveal capillaries probably explains the high incidence of macular involvement. Additional causes of visual loss in toxoplasmosis are tractional distortion of the macula, optic atrophy, cataract, and retinal detachment. Recurrences usually appear at the edge of a quiescent scar, where dormant encysted organisms reactivate.[30,31] (See also Chapter 273.)

Toxoplasmosis acquired postnatally often manifests with isolated ocular involvement.[29,34,35] Solid organ transplant recipients can have evidence of toxoplasmosis infection that is delayed in onset because of the protective effect of trimethoprim-sulfamethoxazole prophylaxis.[36] Although necrotizing retinochoroiditis is the major sequela, early manifestations can be limited to vitritis, anterior uveitis, or retinal vasculitis.[36] Patients with AIDS commonly have multiple active lesions or extensive retinitis.[37]

The clinical diagnosis of ocular toxoplasmosis is confirmed in 50% to 80% of cases by serologic testing.[38,39] Detection of *Toxoplasma*-specific immunoglobulin G (IgG) and IgA in serum or aqueous humor by immunoblotting is the most sensitive method, providing confirmatory evidence in 70% of cases.[39] Identification of *Toxoplasma*-specific gene sequences by polymerase chain reaction (PCR) testing of aqueous humor has reported specificities of 83% to 100% and sensitivities ranging from 28% to 53%.[40,41] Invasive procedures to obtain aqueous humor or ocular tissue may be indicated in severe cases.

Although postnatally acquired active infections usually are treated with antiparasitic drugs, toxoplasmosis is a self-limited disease in immunocompetent individuals in whom long-term benefits of treatment for acute and recurrent toxoplasmic chorioretinitis are uncertain. Current regimens include the following: (1) pyrimethamine plus sulfadiazine and folinic acid; (2) trimethoprim-sulfamethoxazole; and (3) adjunctive clindamycin for coverage against the encysted form.[42–47] In murine models the combination of atovaquone and sulfadiazine is effective.[48] Systemic corticosteroid therapy is indicated when there is visual loss due to inflammation involving the optic nerve or macula.[31] Local destruction of solitary lesions with photocoagulation, cryotherapy, or surgical vitrectomy to remove preretinal membranes or relieve retinal traction may be beneficial in selected cases.[31,49]

Rubella

The most common ocular manifestations of congenital rubella are retinitis, cataract, microphthalmos, and glaucoma.[50–52] Retinitis is characterized by pigmentary mottling of the retinal pigment epithelium (RPE) due to viral invasion, which gives the fundus a “salt-and-pepper” appearance (Fig. 83.3). At birth, the fundi can be normal or can show pigmentary changes. Persistent infection of the RPE causes the pigmentary disturbances to develop or to progress during the first few years of life, after which they tend to remain stable.[51,53] Visual function is normal in patients with involvement of RPE alone. Choroidal neovascularization, macular detachment, and visual loss rarely can be late complications of rubella retinopathy.[54,55] Despite newer technology, cataract surgery frequently is associated with poor visual outcomes owing to postoperative inflammatory complications, glaucoma, and cortical visual impairment.[51,52] Virus can be isolated from lens material for several years after intrauterine infection.[56]

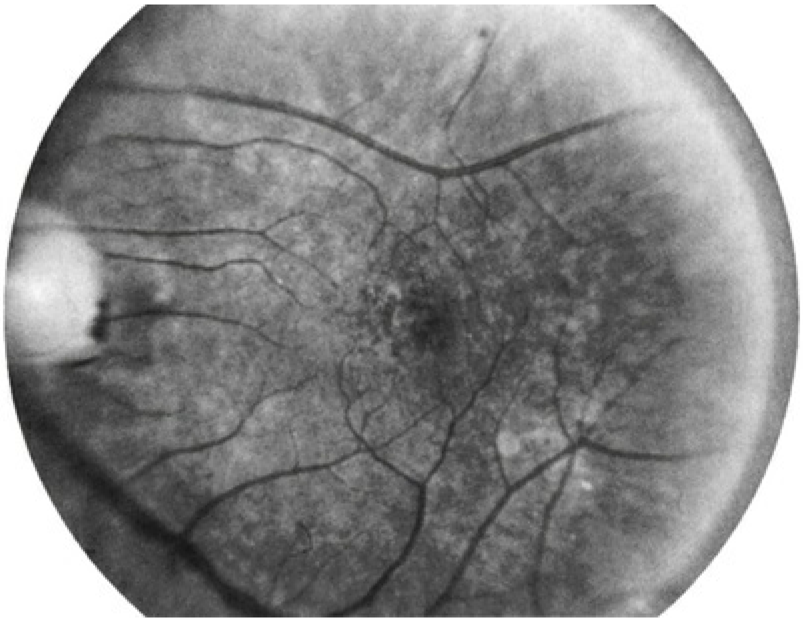

FIGURE 83.3 Fundus photograph shows “salt-and-pepper” retinopathy typical of congenital rubella.

Rubella can contribute to the development of Fuch heterochromic cyclitis, a chronic, unilateral uveitis with mild inflammation that leads to iris atrophy. Assay of aqueous humor revealed IgG rubella antibodies in all 52 patients in one study and the presence of rubella-specific gene sequence in 18% of patients.[57]

Cytomegalovirus

Chorioretinitis is the major ocular sequela in infants congenitally infected with cytomegalovirus (CMV).[58–60] Postinfectious scars appear as geographic areas of chorioretinal atrophy with surrounding hyperpigmentation (Fig. 83.4). Lesions vary in size from 0.5 to 5 mm (½ to 5 disk diameters) and are located in the macula or peripheral retina. Chorioretinal scars are present in 10% to 21% of systemically symptomatic infants but are uncommon in asymptomatic infants. Typically, chorioretinitis in congenital CMV is inactive, but individual congenital cases with postnatal progression and reactivation of chorioretinitis during childhood are reported.[61] Visual loss is associated with macular scarring but can be due to optic atrophy or cortical visual impairment.

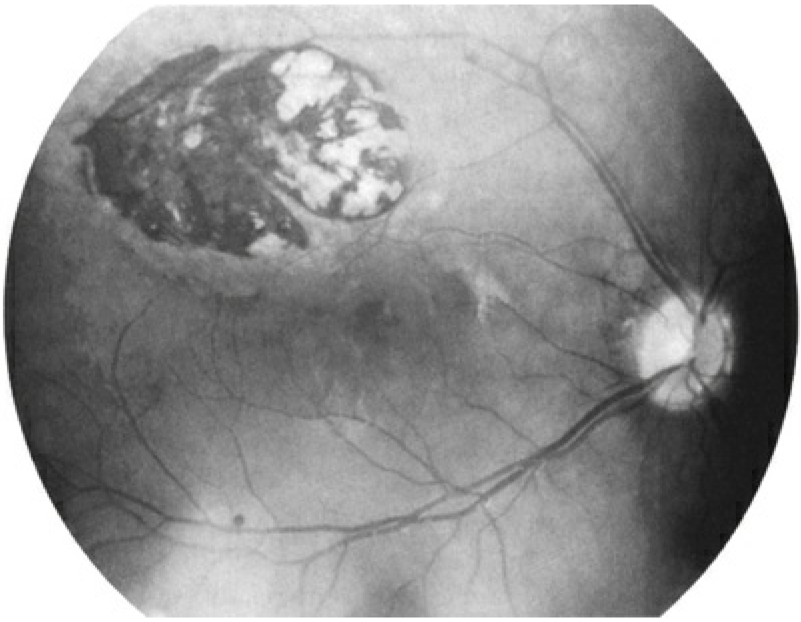

FIGURE 83.4 Fundus photograph shows a geographic chorioretinal scar related to congenital cytomegalovirus infection.

CMV retinitis also can be an acquired infection in immunosuppressed children, such as transplant recipients, those receiving chemotherapy for malignancy, and those with congenital or acquired immunodeficiencies, such as HIV/AIDS.[62–66] In the era of antiretroviral therapy (ART) for HIV, the incidence of CMV retinitis and rates of visual loss, retinal detachment, and mortality have decreased.[67–70] The clinical characteristics of CMV retinitis are similar for patients with and without HIV infection.[71] Early retinitis appears as small white lesions that can be mistaken for cotton-wool spots. The white lesions correspond histologically to areas of intracellular and extracellular edema and necrosis of the retina. These inflammatory changes frequently are associated with intraretinal hemorrhage and vasculitis of nearby retinal vessels, but the overlying vitreous is clear. As infection spreads, the size of the lesions increases along the course of the vessels, and new lesions develop (Fig. 83.5). When lesions heal, the necrotic retina is replaced by glial scar tissue with associated pigmentary clumping.[72–74] Retinitis in the region of the optic nerve and macula is associated with decreased visual acuity and a central visual field defect. Peripheral retinitis causes loss of peripheral visual field, but acuity can be normal.

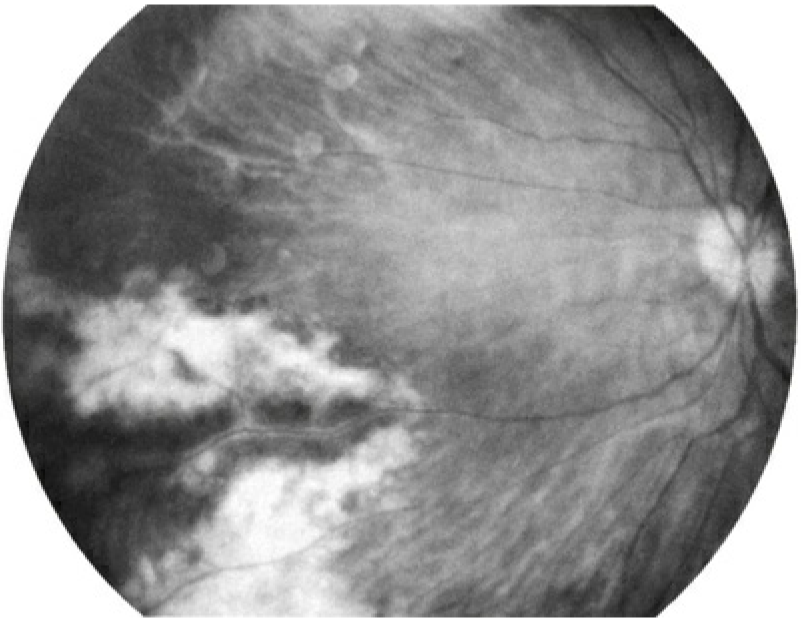

FIGURE 83.5 Fundus photograph shows a localized area of cytomegalovirus retinitis in the peripheral retina; a necrotizing lesion has spread along the course of a retinal vessel and is surrounded by hemorrhage.

Both neonates and immunosuppressed children with CMV chorioretinitis should be treated because active CMV infection can progress to blindness.[74–76] Ganciclovir, foscarnet, and cidofovir are parenteral therapies approved for initial induction and maintenance therapy of CMV retinitis.[77–87] Oral valganciclovir is an alternative to intravenous medications for treatment and maintenance, with fewer side effects.[88] For patients with progressive retinitis or drug-related toxicity (neutropenia, renal disease), local therapy given as an intravitreal injection or a surgically implanted “pellet” should be considered.[89] Local treatment is combined with a systemic antiviral agent to prevent systemic disease and to protect the second eye. Current drugs are virostatic and must be given for long periods of time to prevent progression or recurrence of disease. Children on maintenance chemotherapy for acute lymphoblastic leukemia are at risk for the development CMV retinitis even if they have not received a stem cell transplant.[90] Human monoclonal antibody directed against CMV appears to enhance the benefit of standard antiviral therapy.[91,92]

A subset of patients who become immunologically reconstituted with CD4$^+$ T-lymphocyte counts >100 cells/mm^3 after initiation of ART develop floaters because of vitritis, the incidence of which varies between centers. Complications include papillitis, macular abnormalities, and visual loss.[93,94]

Herpes Simplex Virus

Keratoconjunctivitis can be a manifestation of localized neonatal HSV infection, acquired perinatally. HSV retinitis in neonates generally indicates disseminated or CNS disease.[95,96] The presence of skin lesions, chorioretinitis, and brain abnormalities at birth is suggestive of intrauterine infection.[97] Ocular lesions consist of yellowish areas of necrotizing retinitis, which can be localized or diffuse. Marked vitritis, retinal vasculitis, and persistent fetal vasculature can occur; full-thickness necrosis can lead to optic atrophy and blindness.[98–100] Opsoclonus can be an early sign of encephalitis.[101] Acyclovir intravenously is the treatment of choice.

Congenital Varicella

During the first 20 weeks of pregnancy, approximately 2% of fetuses whose mothers have chickenpox develop an embryopathy.[102,103] Damage is mediated by direct neuropathic effects of the virus or by secondary vasculitis. Clinical features include skin scarring (76%), ocular defects in 51% (chorioretinitis, cataracts, and microphthalmia), skeletal anomalies (49%), and microcephaly and other neurologic deficits (60%).[104,105] Chorioretinitis associated with VZV is indistinguishable ophthalmoscopically from that due to other intrauterine infections. Reduced visual acuity is common because lesions frequently involve the macula.

Herpesvirus Retinochoroiditis and the Acute Retinal Necrosis Syndrome

Postnatally acquired primary varicella or herpes zoster ophthalmicus can be associated with optic disk swelling, macular exudates, multifocal retinitis, and retinal vascular occlusion.[106–108] Acute retinal necrosis (ARN) is an uncommon disease that can occur in immunocompetent or immunocompromised individuals due to VZV, HSV type 1 (HSV-1) or type 2 (HSV-2), CMV, or, rarely, Epstein-Barr virus.[109–114] HSV-2 is the most frequently identified cause of ARN in childhood[115] and often is attributed to reactivation of congenital or neonatal HSV infection.[112,115,116] Characteristic features include multifocal necrotizing retinitis, occlusive arteritis, panuveitis, and rapidly deteriorating vision. Thinning and atrophy of the retina in necrotic areas, combined with vitreous organization and traction, predispose to retinal detachment. Inflammatory optic neuropathy and panuveitis with visual loss can precede the retinopathy.[117] Diagnosis is based on detection of virus-specific gene sequence in aqueous or vitreous samples using the PCR assay. Disease progression is so rapid that visual loss often is irreversible despite aggressive antiviral treatment. However, early treatment with antiviral therapy can prevent further visual loss and the development of ARN in the second eye.[118]

In patients with AIDS, and, less frequently, in immunocompetent individuals, the retinopathy can be atypical, featuring a rapidly progressive necrotizing retinitis and severe bilateral visual loss.[119–122] Although progressive outer retinal necrosis has been emphasized, there is histopathologic evidence of panretinal necrosis.

West Nile Virus

West Nile virus (WNV) is an important cause of arboviral infections of the central nervous system (CNS) in the US.[123] The combined presence of acute encephalitis with multifocal chorioretinitis and vitritis should prompt consideration of WNV or other arbovirus infections. Detection of IgM antibody to WNV in serum confirms the diagnosis.[124,125]

Toxocara canis

Systemic migration of the nematode *Toxocara canis* usually occurs in 1- to 4-year-old children and results in the clinical syndrome of visceral larval migrans.[126,127] Ocular involvement is not concurrent with the visceral larva migrans stage and usually is detected between 4 and 8 years of age. Ocular toxocariasis takes one of the three forms: (1) inflammatory granuloma of the posterior pole; (2) diffuse endophthalmitis; and (3) solitary granuloma of the peripheral retina.[128,129] Common clinical findings include decreased vision, white pupil (leukocoria), and strabismus. The diagnosis is confirmed by the enzyme immunosorbent assay test. The specificity of this assay is high but sensitivity is low, unless a specimen from the aqueous humor is tested.[130] Treatment with periocular or systemic corticosteroids is directed at the inflammatory response incited by the death of larvae.[131] Surgical removal of vitreal membranes and reattachment of the retina can improve vision in individual cases.[132]

Diffuse Unilateral Subacute Neuroretinitis

Diffuse unilateral subacute neuroretinitis is an infection of the eye caused by nematodes endemic to the southeastern and midwestern regions of the US. Although the organisms have not been isolated, migratory larvae have been visualized directly in the subretinal space. One possible worm is *Ancylostoma caninum,* a dog hookworm, which is a common cause of cutaneous larval migrans. Initially, acute visual loss in one eye is noted. Examination of the fundus reveals grey-white lesions in the outer retina that fade over a few days and then reappear elsewhere. Invariably, cells are present in the vitreous, and the optic disk is swollen. Progressive involvement leads to further visual loss, diffuse pigmentary changes, and optic atrophy. Diminution of electroretinographic responses confirms retinal damage and probable visual loss.[133,134] *Baylisascaris procyonis,* a common intestinal raccoon roundworm, is another cause of neural larva migrans and ocular larva migrans. Although neurologic deterioration due to eosinophilic encephalomyelitis predominates clinically, ophthalmologic findings include diffuse unilateral neuroretinitis and choroidal infiltrates.[135,136] Treatment of active vitritis consists of either oral thiabendazole or ivermectin or direct photocoagulation of the larvae.[137–139]

Histoplasma capsulatum

Histoplasmosis of the choroid is believed to be due to invasion by *Histoplasma capsulatum.* Supporting evidence is largely epidemiologic because the organism has not been isolated from choroidal lesions.[140,141] Recent evidence for persistence of *H. capsulatum* DNA sequences in the lesions suggests that these products serve as immunogens and incite chronic inflammation.[142] Viable organisms have been isolated only from immunocompromised patients with endophthalmitis accompanying disseminated infection.[143,144]

This syndrome is characterized by the presence of multiple areas of atrophy in the peripheral retina, referred to as "histo spots." Curvilinear areas of clumped pigment and hypopigmentation surround the disk.[145] Focal scars do not contain viable organisms, but recurrent lymphocytic infiltration predisposes to the development of neovascular membranes and hemorrhagic macular detachment. Treatment options include laser photocoagulation, photodynamic therapy with verteporfin, and intravitreal instillation of corticosteroid, particularly when the macula is threatened.[146–148] Antifungal therapy has no role in the treatment of this disease because there are no actively replicating organisms.

Focal and Multifocal Choroiditis

Infectious organisms that spread hematogenously are more likely to become trapped in the choroid than in other parts of the eye because of high choroidal blood flow and the large number of fenestrated capillaries. Choroidal infiltrates can be single or multiple (Fig. 83.6). Tuberculosis can be associated with a focal choroidal mass, multiple choroidal masses, diffuse or multifocal choroiditis, or retinal vasculitis.[149] Additional infections associated with choroiditis include coccidioidomycosis, cryptococcosis, and nocardiosis.

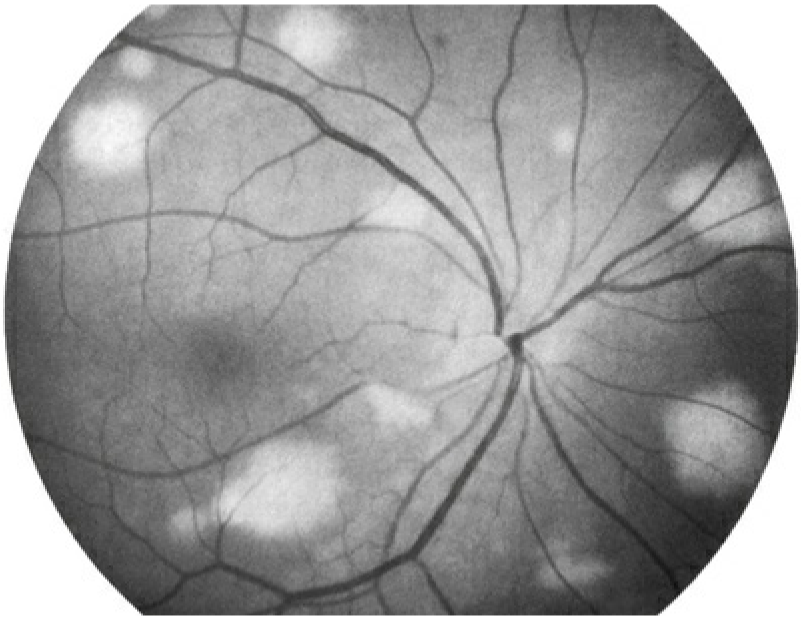

FIGURE 83.6 Fundus photograph shows multifocal choroidal infiltrates deep to the retina; there are no inflammatory cells in the overlying vitreous.

Multifocal choroiditis occurring in the context of AIDS deserves special mention because of its association with life-threatening systemic infections. Etiologic agents include *Pneumocystis jirovecii, Cryptococcus neoformans, M. tuberculosis, Candida, Mycobacterium avium* complex, and *H. capsulatum*.[149–151]

Endophthalmitis

Douglas R. Fredrick

The term *endophthalmitis* is applied to bacterial or fungal infection involving intraocular tissues (retina, uveal tract, or lens) or fluids (vitreous or aqueous). Two broad categories of infectious endophthalmitis are distinguished. *Exogenous* infection results from introduction of organisms into the eye through a surgical or traumatic penetrating wound; *endogenous* (or metastatic) infection is caused by organisms that enter the eye through the bloodstream. Both categories of infection are extremely serious, threatening sight and even loss of the globe.[1–3] Whereas most cases of endophthalmitis in adults occur after surgery or by endogenous routes, most cases of endophthalmitis in children occur after penetrating ocular trauma.[4]

Etiologic Agents

A wide variety of microorganisms can cause endophthalmitis. Gram-positive cocci (both staphylococci and streptococci) are leading pathogens for both exogenous and endogenous endophthalmitis. In recent years gram-positive isolates have become increasingly resistant to antibiotics, including early-generation fluoroquinolones, but resistance to vancomycin and fourth-generation fluoroquinolones remains uncommon.[5,6] *Staphylococcus epidermidis* is the organism most often identified in the postoperative setting and is a frequent agent of posttraumatic endophthalmitis as well.[1,2] Often, *S. epidermidis* infection has a subacute onset 1 week to 1 month after surgery. Neonatal group B streptococcal septicemia can be associated with endogenous endophthalmitis.[3]

The gram-positive anaerobic bacillus *Propionibacterium acnes* is one of the most common causes of endophthalmitis after cataract surgery. Characteristically, *P. acnes* endophthalmitis develops one to several months after surgery and follows a chronic smoldering course.[7] In contrast, *Bacillus cereus* is the most virulent organism inside the eye, capable of destroying the entire retina within hours of introduction by trauma or hematogenous seeding.[8]

Neisseria meningitidis was the most common cause of endogenous endophthalmitis before the advent of antibiotics and still must be recognized as having a predilection for intraocular localization.[3] Nontypable *Haemophilus influenzae* can cause endophthalmitis after accidental trauma and surgery.[9] During the past decade, *Klebsiella pneumoniae* has emerged as the predominant cause of endogenous endophthalmitis in East Asia.[8,10,11] Numerous other gram-negative bacilli (notably *Pseudomonas aeruginosa* and *Escherichia coli*) have been associated with both exogenous and endogenous endophthalmitis, especially after trauma or surgery, and in individuals with underlying conditions.[1,3,12]

Candida albicans bloodstream infection (BSI) remains the most common fungal precursor of endogenous endophthalmitis, although this complication appears to be decreasing in frequency with earlier initiation of systemic treatment for candidemia and invasive candidiasis.[1,13–15] Meta-analysis of neonatal *Candida* BSI showed 3% prevalence of endophthalmitis.[14] Non-*albicans Candida* spp. and a variety of other fungi (including *Aspergillus* and *Fusarium, Alternaría*, and *Scedosporium* spp.) have been implicated in both endogenous and exogenous endophthalmitis, especially in posttraumatic cases or immunocompromised hosts.[16,17] Fungal endophthalmitis tends to follow a more indolent course than that of most bacterial infections.

Epidemiology and Host Factors

Postoperative endophthalmitis most often follows cataract extraction but can be associated with any form of intraocular procedure or extraocular operations, such as strabismus repair (in which organisms presumably are introduced into the globe by inadvertent needle perforation of the sclera).[18,19] The rate of endophthalmitis after pediatric intraocular surgery is similar to that found in adults—approximately 1 in 1000 cases.[20–22] Extracapsular cataract surgery with intraocular lens implantation (increasingly being performed in childhood) predisposes particularly to chronic endophthalmitis caused by *P. acnes.*[7] A recent trend in cataract surgery toward use of unsutured "self-sealing" incisions through temporal clear cornea (as opposed to the superior limbus) has been associated with a small but substantial increase in the frequency of postoperative endophthalmitis.[23]

Filtering operations for glaucoma (which produce a fistulous connection for aqueous flow through the corneoscleral limbus between the anterior chamber and a conjunctival bleb) lower the physical resistance of the globe to invasion by microorganisms, creating a higher risk for intraocular infection that can persist for decades if the drainage tract remains patent. The frequency of late bleb-related endophthalmitis appears to have increased considerably in children as well as in adults because of increasing use of periocular antifibrotic agents (mitomycin C or 5-fluorouracil) administered intraoperatively or postoperatively. These drugs improve the rate of successful lowering of intraocular pressure after filtering surgery but tend to result in blebs that are large and thin-walled and, thus, particularly vulnerable to bacterial invasion.[9,24]

A recently recognized inflammatory condition that occurs after intraocular surgery, toxic anterior segment syndrome, can be confused with postoperative infectious endophthalmitis.[25] In this condition, toxins on surgical instruments that have been improperly sterilized lead to an inflammatory reaction within days after the anterior segment surgery. The diagnosis is made only after appropriate diagnostic aqueous and vitreous samples have been obtained for culture and sensitivity and intraocular empiric antibiotics have been administered because the consequence of not treating an infectious process could be devastating.

Endophthalmitis is a major concern after any penetrating trauma to the globe, especially in childhood, when contamination of the causative instrument with soil, saliva, or fecal material is common.[16,26,27] Occult penetration of the globe by a needle, thorn, or similarly shaped object can be unsuspected in a nonverbal child until days later when infection leads to obvious inflammatory signs. In a child with posttraumatic endophthalmitis, the possibility of an intraocular foreign body (which must be removed surgically) must be considered, and should be excluded, if necessary, with ultrasonographic or radiographic imaging.

Endogenous endophthalmitis usually occurs in a host who is already known to have BSI or is immunocompromised, but occasionally, ocular involvement is the first indication of the underlying problem.[3] Endocarditis and meningitis are the most important localized infections associated with endophthalmitis. Diabetic patients have the propensity for retinal spread of *K. pneumoniae* from hepatic abscesses and of *E. coli* from a urinary tract infection.[11,12] Intravenous drug abusers have increased risk for intraocular fungal infection and also for devastating *B. cereus* endophthalmitis.[3,8]

Although otherwise healthy persons are occasionally affected, most cases of endogenous candidal endophthalmitis are nosocomial, occurring in association with indwelling intravascular catheters, use of broad-spectrum antibiotics, or immunosuppressive or major surgical treatment. Infants with intraocular candidiasis or bacterial endophthalmitis usually have a history of premature birth and pulmonary disease.[13]

Pathophysiology

Microbial proliferation begins and remains concentrated in the aqueous or vitreous fluid in most cases of exogenous endophthalmitis. Damage to the retina and other intraocular structures occurs secondarily from exposure to toxins elaborated by the organisms and inflammatory cells.

By contrast, endogenous endophthalmitis typically originates in tissue within which a septic embolus has lodged.[3] When this process occurs in a small terminal branch of a vessel, ocular infection begins as either a microabscess in the iris or a focal lesion of retinitis or choroiditis. Diffuse involvement of the anterior ocular segment can develop rapidly after invasion of the iris, but posterior extension usually remains limited in such cases. Spillover of organisms and inflammatory cells from infected tissues of the posterior ocular segment leads to involvement of the vitreous, which subsequently can remain localized or become diffuse, extending ultimately to the anterior segment, sclera, and orbit (panophthalmitis). Occlusion of the central retinal artery by a large embolus can result in ischemia followed by massive dissemination of organisms directly into the retina that can lead to irreversible blindness within a short time.

Clinical Manifestations

The first external sign of endophthalmitis usually is injection of conjunctival vessels. Injection can be striking and associated with marked conjunctival and eyelid edema, or so mild that it scarcely attracts attention. Endophthalmitis must therefore be included in the differential diagnosis of every “red eye.” Careful inspection of the anterior segment with a hand light usually permits identification of a whitish *hypopyon,* which results from layering of abundant leukocytes from aqueous fluid onto the surface of the iris or in the most dependent portion of the anterior chamber (Fig. 84.1). Sometimes, however, the only readily identifiable sign in the anterior segment is blue-grey haziness or loss of clarity in visualization of the iris and the pupil, often accompanied by diminished or absent reactivity to light. Vision usually is reduced.

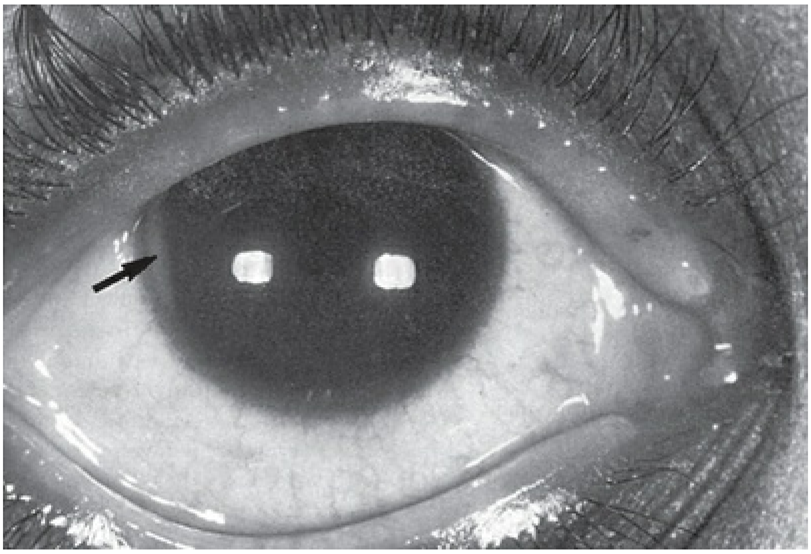

FIGURE 84.1 Right eye of a 15-year-old girl with acute meningococcal meningitis and bilateral endophthalmitis. Note the small hypopyon *(arrow),* layered temporally in the anterior chamber because

she had been lying on her right side.

Low-grade endophthalmitis localized to the posterior segment (including most cases of intraocular candidiasis) may produce no external signs. Typically, there is decreased clarity of ophthalmoscopic visualization and dimming of the fundus red reflex, resulting from vitritis, and visual acuity is reduced. In some cases, however, the problem only becomes evident when detailed examination of the fundus through a dilated pupil reveals the presence of one or more small whitish chorioretinal or vitreal infiltrates with indistinct borders.

Diagnostic Evaluation

Suspicion of endophthalmitis mandates consultation with an ophthalmologist, who can confirm the diagnosis, quantify the vision loss, and determine the extent of posterior-segment involvement (employing B-scan ultrasonography if the fundus cannot be visualized).

In the context of well-defined systemic infection with an identifiable organism, generally it is not necessary to perform additional microbiologic studies when making the diagnosis of endophthalmitis.[2] Otherwise, aspiration of ocular fluid for culture is required. If the patient is cooperative or immobilized easily, aqueous fluid (about 0.1 mL) can be obtained at the bedside with the use of a 27- or 30-gauge needle on a 1-mL syringe. Aspiration of the vitreous is a surgical procedure best performed in the operating room for children (Fig. 84.2). Vitreous culture has a substantially higher yield than aqueous culture in exogenous and posteriorly localized endogenous infection.[3,28,29] When fungal infection is suspected, polymerase chain reaction testing of vitreous aspirate can provide rapid confirmation of etiology.[30,31]

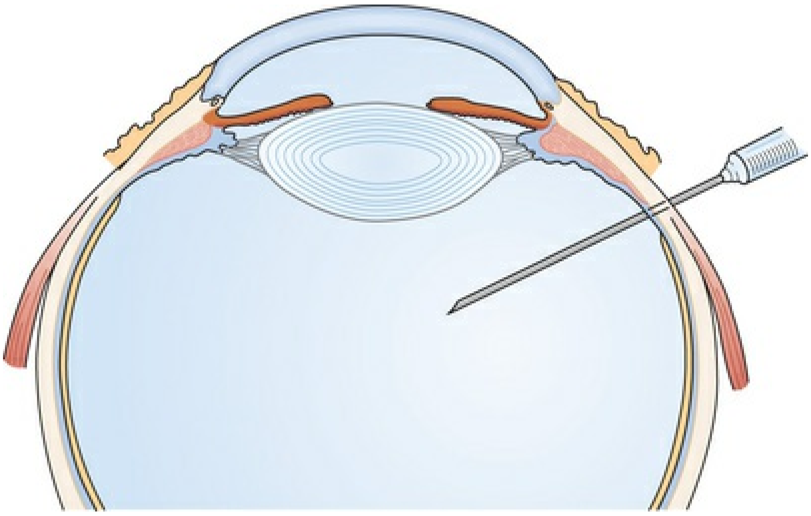

FIGURE 84.2 Diagrammatic illustration of needle passing through the pars plana of the ciliary body for diagnostic aspiration of vitreous or intravitreal injection of antibiotic. (Adapted from Bohigian GM. Endophthalmitis. In: Krupin T, Kolker AE, Rosenberg LF [eds]. Complications in Ophthalmic Surgery, 2nd ed. St. Louis, Mosby, 1999, pp. 19–36.)

In about 25% to 50% of cases of presumed infectious endophthalmitis, eye fluid cultures are sterile. For maximal yield, aspirates should be inoculated promptly into appropriate media, including media used for isolation of anaerobic and fungal organisms. Inoculation of fluid specimens into blood culture bottles also has been used successfully.[1]

With endophthalmitis of unknown origin, multiple blood cultures should be performed, followed by an exhaustive search for remote infections and predisposing conditions, including occult ocular trauma, diabetes, acquired immunodeficiency syndrome, and other immunodeficiency disorders.

Management

Antimicrobial agents for endophthalmitis can be delivered by a variety of routes. Intravenous antibiotic administration is the mainstay of treatment for endogenous bacterial infection.[3,10] The choice of drugs should be based on known or presumed susceptibility of documented or suspected pathogens, with dosage and duration at levels appropriate for meningitis (or greater if required for associated infection at another site). Endogenous fungal endophthalmitis usually responds well to treatment with intravenous amphotericin B; however, newer agents such as voriconazole (which can yield therapeutic intraocular concentration after oral as well as intravenous administration) are increasingly viewed as appropriate and possibly preferable alternative therapies.[32,33] If fungal chorioretinitis extends into the vitreous cavity, intravitreal injection with either amphotericin B (5–10 µg) or voriconazole (100 µg) is necessary, and vitrectomy may be required to remove fungal burden and inflammatory cells to minimize risk for retinal damage.

In the past, many cases of exogenous endophthalmitis were cured with combined intravenous, subconjunctival, and topical antibiotics, but intravitreal administration is now regarded as the most important route of drug delivery for this condition (see Fig. 84.2).[1,18,19] Initially, only a single injection is given (immediately after aspiration of vitreous for culture), followed by one or more additional injections if response to the first is incomplete. Gentamicin and cefazolin were formerly the intraocular antibiotics used most often, but growing concerns about aminoglycoside retinal toxicity and drug-resistant organisms have led to a shift toward other agents, particularly ceftazidime and vancomycin (Table 84.1; see also Table 294.4).[34]

TABLE 84.1

Intravitreal Injection for Endophthalmitis

Drug	Dose[a] (mg)	Comment
Vancomycin	1	Unless gram-positive bacteria can be excluded
Amikacin	0.4	Now seldom used because of potential retinal toxicity
Ceftazidime	2.25	Preferred agent for gram-negative coverage
Amphotericin B	0.005	If fungus suspected
Voriconazole	0.1	Increasingly used alternative to amphotericin
Dexamethasone	0.4	Recommended for anti-inflammatory effect by some authorities

[a] Each drug should be diluted to provide the indicated dose in a volume of 0.1 mL and should be injected using a separate 1 mL syringe.

Recommendations from references 1 and 18, and Hariprasad SM, Mieler WF, Flynn HW, et al. Advances in endophthalmitis management. Instruction course syllabus, American Academy of Ophthalmology Annual Meeting, Las Vegas, Nevada, 2006.

Controversy persists regarding the need for concurrent use of multiple routes of therapy.[35] Outcomes reported after combined intravitreal and systemic administration of antibiotics are similar to those seen with intravenous treatment alone in endogenous infections and with intravitreal treatment alone in most exogenous infections.[3,10,36,37] Many experienced clinicians continue to employ both modalities. Fourth-generation fluoroquinolones such as moxifloxacin can achieve therapeutic intraocular levels after oral administration (initial loading dose in an adult of 400 mg twice daily, followed by 400 mg once daily for 1 to 2 weeks) and have a favorable spectrum of coverage, making them an attractive used adjunct to intravitreal injection.[38] Moxifloxacin has become the antibiotic of choice for oral administration because of its high intraocular penetration, but caution should be exercised when used in children because of its association with potential tendon rupture. Minimal inhibitory concentrations for methicillin-resistant *S. aureus* (MRSA) are at least 10-fold those for methicillin-susceptible *S. aureus*. Intravitreal vancomycin is used for MRSA infection. Subconjunctival antibiotics (given as once- or twice-daily injections) are also sometimes used, although data to indicate incremental benefit are lacking. Cephalosporins often are used for treatment after discharge from the hospital, but intraocular and intravenous therapy is required at the time of initial diagnosis. Many clinicians also include corticosteroid agents (intraocular, subconjunctival, topical, systemic, or a combination) in the regimen in an attempt to reduce ocular inflammatory damage. No adverse effect on control of infection from this practice has been documented when appropriate antimicrobial therapy is given.[1,2,18]

The role of vitrectomy in the management of exogenous endophthalmitis was clarified by the results of a major multicenter, randomized clinical trial.[37] The investigators compared outcomes from treatment of postoperative endophthalmitis after cataract surgery using intravitreal antibiotics (amikacin and vancomycin) with or without immediate surgical removal of most of the infected vitreous. Vitrectomy provided significant benefit only when initial visual acuity was severely reduced to the level of light perception only. With better initial vision, outcomes were the same with and without vitrectomy. Vitrectomy with removal of infected lens material appears to be required for cure of most cases of chronic endophthalmitis caused by *P. acnes*.[7] Most authorities continue to view vitrectomy as warranted for endophthalmitis associated with penetrating trauma and glaucoma filtering blebs.[2,18]

Occasionally, even after intensive treatment, an eye is left blind and intractably inflamed by endophthalmitis. In such cases, it may be necessary to remove the entire ocular contents surgically (evisceration) or to remove the complete globe (enucleation).

Outcome

With current optimal therapy, the prognosis for infectious endophthalmitis is good. Recovery is the rule in (1) postoperative endophthalmitis due to *S. epidermidis* and *P. acnes;* (2) endogenous *Candida* endophthalmitis; and (3) endogenous bacterial endophthalmitis that shows either primarily anterior-segment or only focal posterior-segment involvement at the time of diagnosis, regardless of organism.[1,3,39] Mild to moderate permanent visual loss is common even in these favorable cases, however.

In situations other than those mentioned, endophthalmitis remains a grave disorder. Cases of bacterial infection due to trauma or to a hematogenous spread from other sites of infection that show diffuse posterior-segment involvement have a particularly poor prognosis, typically leaving the patient with a nonseeing eye or no eye at all.[3,8,16]

Overall, with current therapeutic methods, useful vision (finger-counting or better) is retained in about 60% of eyes treated for acute or subacute exogenous bacterial endophthalmitis and in 40% of eyes treated for endogenous bacterial endophthalmitis. These outcomes have remained unchanged over several decades.[3,25,40]

Prevention

Preoperative application of 1 drop of 5% povidone-iodine (half-strength dilution of the common commercially available solution) to the ocular surface has been shown to reduce the conjunctival bacterial population significantly and appears to lower the incidence of postoperative endophthalmitis.[21,41] It also remains common practice to administer a single subconjunctival injection of antibiotic (usually an aminoglycoside or a cephalosporin) at the conclusion of intraocular surgery and to prescribe a topical solution, to be applied several times a day for 1 week or longer. Use of moxifloxacin topically before and after surgery has been increasing. A minority of surgeons add antibiotic to the infusion fluid that circulates through the eye during cataract or vitrectomy surgery. Recent studies support the injection of antibiotic into the anterior chamber at the conclusion of surgery, but this approach has not been widely adopted in North America.[42]

Intensive prophylaxis against endophthalmitis is employed by most ophthalmologists after penetrating trauma. Intravenously administered vancomycin plus ceftazidime has largely replaced the traditional use of a first-generation cephalosporin, with or without an aminoglycoside.[2] Oral administration of a fluoroquinolone (e.g., moxifloxacin) can achieve therapeutic drug levels in the vitreous and reasonably good coverage for common infecting organisms, except MRSA and some coagulase-negative staphylococci.[43]

Some authorities recommend intravitreal injection as a preventive measure in cases of traumatic endophthalmitis that are likely to involve heavy contamination.[2,22,26] Culture of foreign material removed from the eye, aqueous or vitreous, exposed uveal tissue, or the conjunctiva (in roughly descending order of usefulness) at the time of surgical wound repair can provide valuable information for optimizing treatment should endophthalmitis develop.

Because of the risk for endophthalmitis, conjunctivitis that develops in an eye with a glaucoma filtering bleb should be treated promptly and aggressively with topical and, possibly, systemic antibiotics.[9]

Ophthalmologic evaluation to rule out ocular involvement in patients with *Candida albicans* fungemia or deep tissue infection appears to be justified, given the paucity of external signs heralding its development.[15] Ophthalmologic screening has a very low yield in patients who have fever of unknown origin or in whom *Candida* is isolated only from a superficial site or a catheter, and so is no longer recommended.

Preseptal and Orbital Infections

Ellen R. Wald

The practitioner frequently has the opportunity to manage the child for whom the chief complaint is a "swollen eye" (Fig. 85.1). Some children have trivial or self-limited disorders, but others can have sight- or life-threatening problems. Noninfectious causes of the swollen eye can often be distinguished from infectious causes by a detailed history of the onset and progression of the eye swelling. Infectious causes of eye swelling are usually acute in presentation. Differentiating preseptal (common) and orbital (rare) causes of eye swelling is critical to management and can usually be accomplished on the basis of the physical examination.

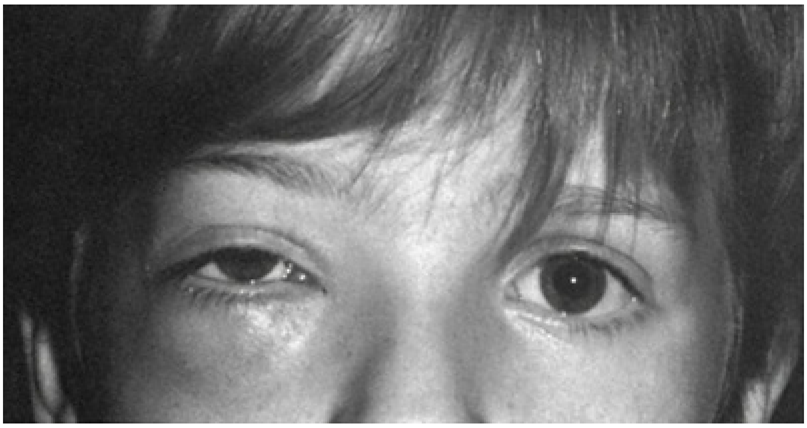

FIGURE 85.1 A 10-year-old boy with the complaint of swollen eye.

Differential Diagnosis

The noninfectious causes of swelling of or around the eye include (1) blunt trauma (leading to the proverbial "black" eye), (2) tumor, (3) local edema, and (4) allergy. In cases of blunt trauma, history provides the key to the diagnosis. Eyelid swelling continues to increase for 48 hours and then resolves over several days. Tumors that characteristically involve the eye include hemangioma of the lid, ocular tumors such as retinoblastoma and choroidal melanoma, and orbital neoplasms such as neuroblastoma and rhabdomyosarcoma.[1] Other tumors reported to cause orbital involvement are Langerhans cell histiocytosis and granulocytic sarcoma.[2,3] Tumors usually cause gradual onset of proptosis in the absence of inflammation. Orbital pseudotumor, an autoimmune inflammation of the orbital tissues, manifests as eyelid swelling, red eye, pain, and decreased ocular motility.[4] Hypoproteinemia and congestive heart failure cause eyelid swelling due to local edema; characteristic findings are bilateral, boggy, nontender, nondiscolored soft tissue swelling. Allergic inflammation includes angioneurotic edema or contact hypersensitivity.[5] Superficially, allergic inflammation can resemble acute infection; however, the presence of pruritus and the absence of tenderness are helpful distinguishing characteristics.

Pathogenesis

The anatomy of the eye is important for an understanding of its susceptibility to spread of infection from contiguous structures. Veins that drain the orbit, the ethmoid and maxillary sinuses, and the skin of the eye and periorbital tissues (Fig. 85.2) constitute an anastomosing and valveless network.[1] This venous system provides opportunities for spread of infection from one anatomic site to another and predisposes to involvement of the cavernous sinus.

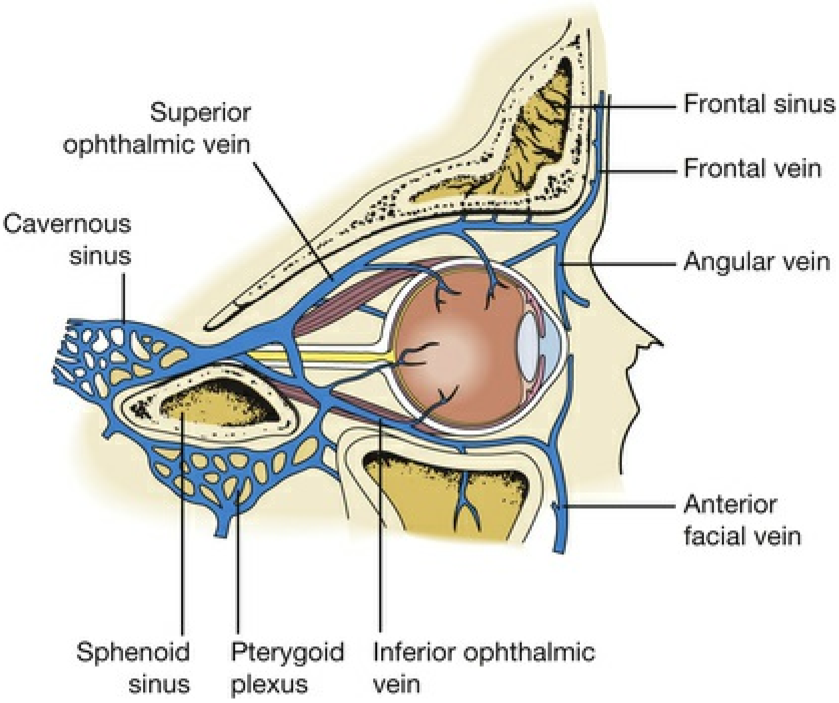

FIGURE 85.2 The valveless venous system of the orbit and its many anastomoses.

Fig. 85.3 demonstrates the relationship between the eye and the paranasal sinuses. The roof of the orbit is the floor of the frontal sinus, and the floor of the orbit is the roof of the maxillary sinus. The medial wall of the orbit is formed by the frontal maxillary process, the lacrimal bone, the lamina papyracea of the ethmoid bone, and a small part of the sphenoid bone.[6] Infection originating in the mucosa of the paranasal sinuses can spread to involve the bone (osteitis with or without subperiosteal abscess) and the intraorbital contents. Orbital infection can occur through natural bony dehiscences in the lamina papyracea of the ethmoid or frontal bones or through foramina through which the ethmoidal arteries pass.[5]

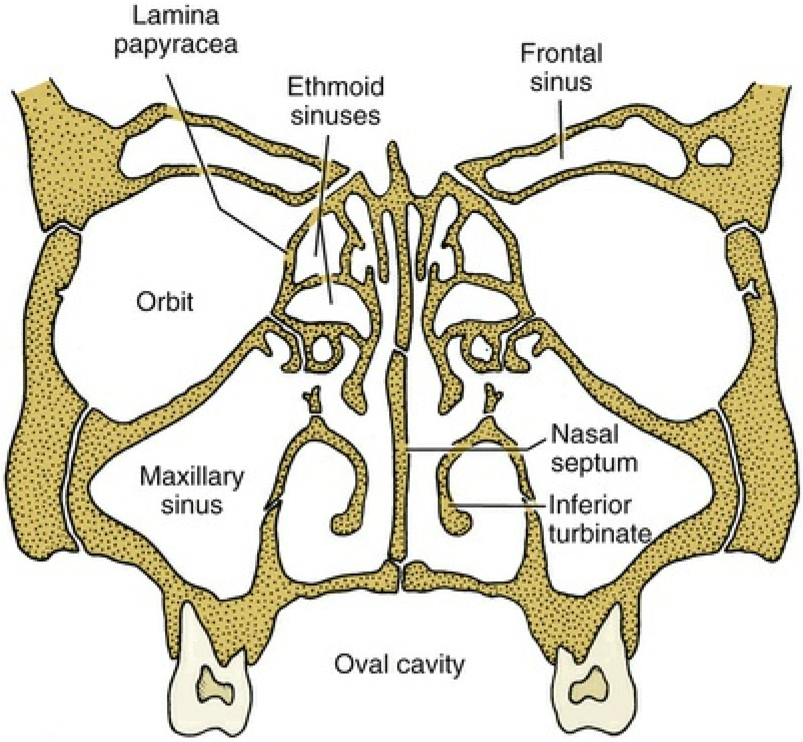

FIGURE 85.3 The relationship between the eye and the paranasal sinuses is shown schematically. The roof of the orbit, the medial wall, and the floor are shared by the frontal, ethmoid, and maxillary sinuses, respectively. (Redrawn from Shapiro ED, Wald ER, Brozanski BA. Periorbital cellulitis and paranasal sinusitis: a reappraisal. Pediatr Infect Dis J 1982;1:91–94.)

Fig. 85.4 shows the position of the orbital septum, a connective tissue extension of the periosteum (or periorbita) that is reflected into the upper and lower eyelids. Infection of tissues anterior to the orbital septum are described as *periorbital* or *preseptal*.[7] The septum provides a nearly impervious barrier to spread of infection to the orbit. Although preseptal cellulitis or periorbital cellulitis (the terms may be used interchangeably) often is considered a "diagnosis," either term is an inadequate diagnostic label unless accompanied by a modifier that indicates likely pathogenesis. In the remainder of this chapter, *preseptal cellulitis* is the preferred term.

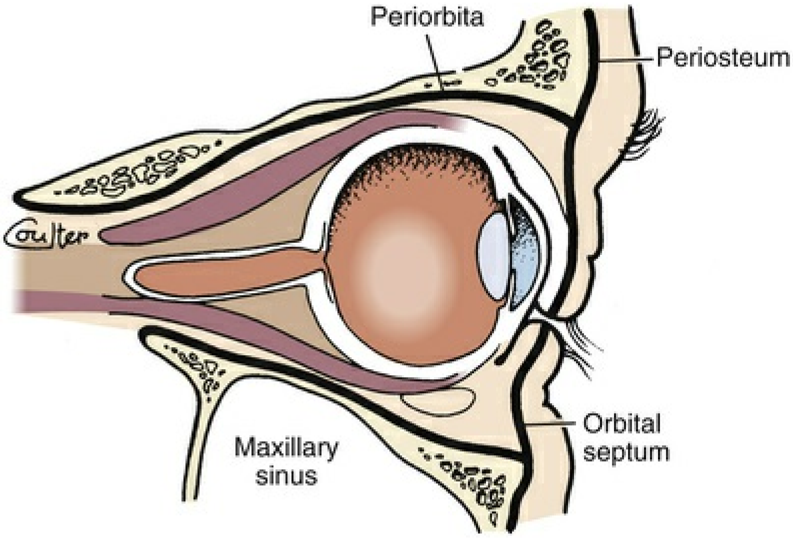

FIGURE 85.4 The orbital septum is a connective tissue extension of the periosteum that is reflected into the upper and lower lid. (Redrawn from Shapiro ED, Wald ER, Brozanski BA. Periorbital cellulitis and paranasal sinusitis: a reappraisal. Pediatr Infect Dis J 1982;1:91–94.)

Infectious causes of preseptal cellulitis occur in the following three settings: (1) secondary to a localized infection or inflammation of the conjunctiva, eyelids, or adjacent structures (e.g., conjunctivitis, hordeolum, acute chalazion, dacryocystitis, dacryoadenitis, impetigo, traumatic bacterial cellulitis); (2) secondary to hematogenous dissemination of nasopharyngeal pathogens to the periorbital tissue; and (3) as a manifestation of inflammatory edema in patients with acute sinusitis (Box 85.1).[7]

Box 85.1

Infectious Causes of Preseptal and Orbital Cellulitis

Preseptal Cellulitis

Localized infection of the eyelid or adjacent structure

Conjunctivitis

Hordeolum

Dacryoadenitis

Dacryocystitis

Bacterial cellulitis (trauma)

Hematogenous dissemination

Bacteremic periorbital cellulitis

Acute sinusitis

Inflammatory edema

Orbital Cellulitis

Acute sinusitis

Subperiosteal abscess

Orbital abscess

Orbital cellulitis

Cavernous sinus thrombosis

Hematogenous dissemination

Endophthalmitis

Traumatic inoculation

Endophthalmitis

Infections behind the septum that cause eye swelling include subperiosteal abscess, orbital abscess, orbital cellulitis, cavernous sinus thrombosis, panophthalmitis, and endophthalmitis. Although all of these entities can be labeled *orbital cellulitis,* a systematic approach allows a more specific diagnosis, thereby directing management. Infections intrinsic to the eye (i.e., conjunctivitis, keratitis, endophthalmitis, and panophthalmitis) are discussed in Chapters 80 through 84.

Preseptal Infections

Conjunctivitis

Conjunctivitis is the most common disorder of the eye for which children are brought for medical care. In most cases, the lids are crusted and thickened with hyperemic conjunctiva. The usual causes of conjunctivitis in children older than neonates but less than 6 years old are *Haemophilus influenzae* (nontypable) and *Streptococcus pneumoniae.*[8,9] In approximately 20% to 25% of children with conjunctivitis due to *H. influenzae,* acute otitis media is a complicating feature. In this case, systemic antibiotics are preferable to topical ophthalmic preparations. Adenovirus is the most common cause of viral conjunctivitis in children older than 6 years and frequently is associated with pharyngitis.[10] Occasionally young children with adenovirus infection have diffuse swelling of the lids that can be mistaken for a more serious problem.[11] Other viral causes of hemorrhagic conjunctivitis are enterovirus 70 and coxsackievirus A24 (see Chapter 80).

Hordeolum and Chalazion

An *external hordeolum,* or stye, is a bacterial infection of the gland of Zeis or Moll (sebaceous gland or sweat gland, respectively) associated with a hair follicle on the eyelid. In most cases, infection is localized and points to the lid margin as a pustule or inflammatory papule. The lid can be slightly swollen and erythematous around the area of involvement. An external hordeolum usually lasts a few days to a week and resolves spontaneously.

An *internal hordeolum* is a bacterial infection of a meibomian gland, a long sebaceous gland whose orifice is at the lid margin.[12] The infection usually causes inflammation and edema of the neck of the gland, which can result in obstruction. If there is no obstruction, infection points to the lid margin. If obstruction is present, infection points to the conjunctival surface of the eye.[12] Sometimes the swelling caused by an acute internal hordeolum is diffuse rather than localized, and a pustule is not obvious on the lid margin. To clarify the cause, it is necessary to evert the eyelid and examine the tarsal conjunctiva. A tiny, delicate pustule is diagnostic of an internal hordeolum.

The usual cause of acute internal or external hordeola is *Staphylococcus aureus.* An antibiotic ophthalmic ointment containing bacitracin can be applied to the site of infection. The main purpose of the topical therapy is to prevent spread of infection to adjacent hair follicles. Warm compresses may facilitate spontaneous drainage.

In contrast to the internal hordeolum, a *chalazion* manifests as a persistent (>2 weeks in duration), nontender, localized bulge or nodule (3–10 mm) in the lid; the overlying skin is completely normal. It is a sterile lipogranulomatous reaction. When a chalazion is large and causes local irritation, incision may be required.

Dacryoadenitis

Dacryoadenitis is an infection of the lacrimal gland. Sudden onset of soft tissue swelling that is maximum over the outer portion of the upper lid margin is typical. Occasionally, the eyeball is erythematous and the eyelid swollen, and the patient can have remarkable constitutional symptoms. The location of the swelling is a distinguishing characteristic (Fig. 85.5). When dacryoadenitis is caused by viral infection (mumps virus, Epstein-Barr virus,[13] cytomegalovirus, coxsackievirus, echoviruses, or varicella-zoster virus), the area is only modestly tender.[14] By contrast, when the infection is caused by bacterial agents, discomfort is prominent. In addition to *S. aureus,* which is the most common cause of bacterial dacryoadenitis, etiologic agents include streptococci, *Chlamydia trachomatis, Brucella melitensis,* and, occasionally, *Neisseria gonorrhoeae.*[15,16] Fungal and rare parasitic infections of the lacrimal gland have been reported, including those with *Cysticercus cellulosae* and *Schistosoma haematobium.*[14] If parenteral therapy is required for suspected bacterial dacryoadenitis due to *S. aureus,* nafcillin (150 mg/kg/day divided into doses every 6 hours) is appropriate. If methicillin-resistant *S. aureus* (MRSA) is suspected, vancomycin (60 mg/kg divided into doses every 6 hours) should be initiated. Oral treatment of acute dacryoadenitis is undertaken with a semisynthetic penicillin such as dicloxacillin (100 mg/kg/day divided into doses every 6 hours), cephalexin or cefadroxil (100 or 50 mg/kg/day, respectively, divided into doses every 6 or 12 hours, respectively), trimethoprim-sulfamethoxazole (based on 40 mg/kg/day of trimethoprim divided into doses every 12 hours), or clindamycin (40 mg/kg/day divided into doses every 6 hours). Treatment is continued until all signs and symptoms have disappeared.

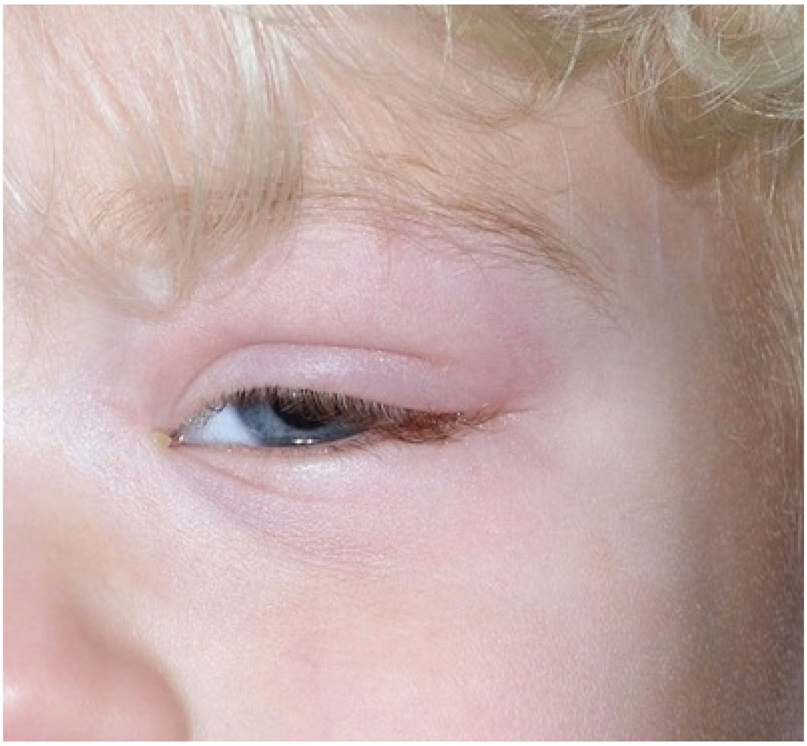

FIGURE 85.5 A patient with dacryoadenitis during a viral illness. The nontender swelling over the lateral portion of the left upper lid resolved without antibiotic treatment. (Courtesy of J. H. Briené.)

The differential diagnosis of swelling of the upper outer aspect of the eyelid includes inflammatory noninfectious problems such as Sjögren syndrome and sarcoidosis as well as benign and malignant tumors.[14]

Dacryocystitis

Dacryocystitis is a bacterial infection of the lacrimal sac. Although uncommon, dacryocystitis can occur at any age as a bacterial complication of a viral upper respiratory tract infection (URI). Because of the course traversed by the lacrimal duct, which drains to the inferior meatus within the nose, it is surprising that the duct and sac are not infected more often. Delayed opening of the duct, inspissated secretions, and anatomic abnormalities lead to disproportionate representation of infants younger than 3 months among children with dacryocystitis.

Patients with dacryocystitis usually have had a viral URI for several days. They then experience fever and impressive erythema and swelling in addition to exquisite tenderness, which is most prominent in the triangular area just below the medial canthus[17] (Fig. 85.6). Pressure over the lacrimal sac causes considerable discomfort but can result in expression of purulent material from the lacrimal puncta. Common causative organisms are gram-positive cocci. *S. pneumoniae* is most common in neonates, although *S. aureus, H. influenzae,* and *Streptococcus agalactiae* also have been reported.[15,18] *S. aureus* and *S. epidermidis* are most commonly implicated in acquired dacryocystitis in the older patient.[19] It is important to obtain material from the punctum because other organisms (including enteric gram-negative bacilli, anaerobic bacteria, and yeast) occasionally have been observed. Unusual pathogens, such as *Pasteurella multocida* and *Aeromonas hydrophilia,* have been reported rarely.[20]

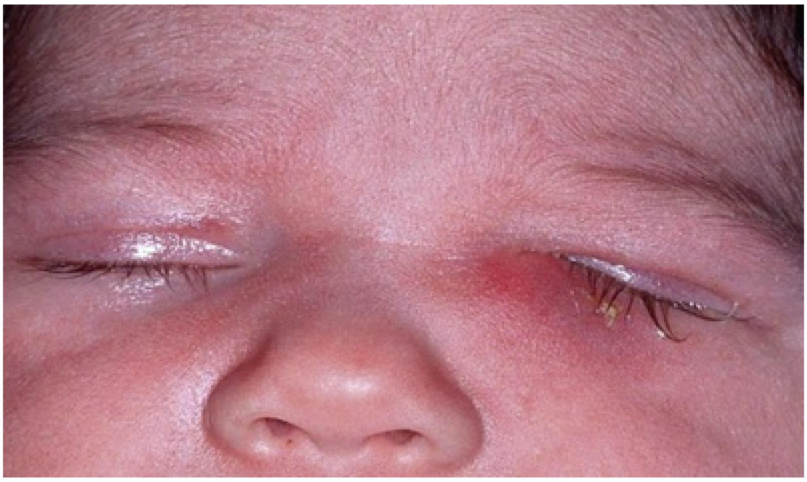

FIGURE 85.6 Dacrocystitis in an infant. The area at or beneath the medial canthus is erythematous, indurated, and exquisitely tender. (Courtesy of J. H. Briené.)

Most patients with dacryocystitis require admission to hospital. Often they appear ill or toxic. Because of the potential for any case of bacterial facial cellulitis to result in cavernous sinus thrombosis, therapy with parenteral antibiotics is indicated until the infection begins to subside. Nafcillin (at a dose of 150 mg/kg/day divided into doses every 6 hours) or cefazolin (at a dose of 100 mg/kg/day divided into doses every 8 hours) is appropriate. In penicillin-allergic patients, or when MRSA is suspected, vancomycin (60 mg/kg/day divided into doses every 6 hours) suffices. After substantial improvement is observed in local findings, an oral agent can be substituted to complete a 10- to 14-day course of therapy.

The role of nonmedical management of dacryocystitis is controversial. Although surgical manipulation of the lacrimal duct is not necessary for most patients, both probing of the duct and incision and drainage have been reported to be successful in neonates.[18] Incision and drainage and direct application of antibiotics inside the sac have been promoted by some practitioners who care for older children and adults.[21]

Preseptal Cellulitis After Trauma

Occasionally, preseptal cellulitis results from secondary bacterial infection of sites of local skin trauma (including insect bites) or with spread of infection from a focus of impetigo. The traumatic injury can be extremely modest or completely inapparent. Loosely bound periorbital soft tissues permit impressive swelling to accompany minor infection. The overlying skin can be bright red with subtle textural changes, or intense swelling can lead to a shiny appearance (Fig. 85.7). Some patients have fever, but many are afebrile despite dramatic local findings. The peripheral white blood cell count is variable. In these cases, cellulitis, similar to that on any other cutaneous area, is caused by *S. aureus* (including MRSA) or group A *Streptococcus*.[22,23] This is one of the most common causes of preseptal cellulitis.

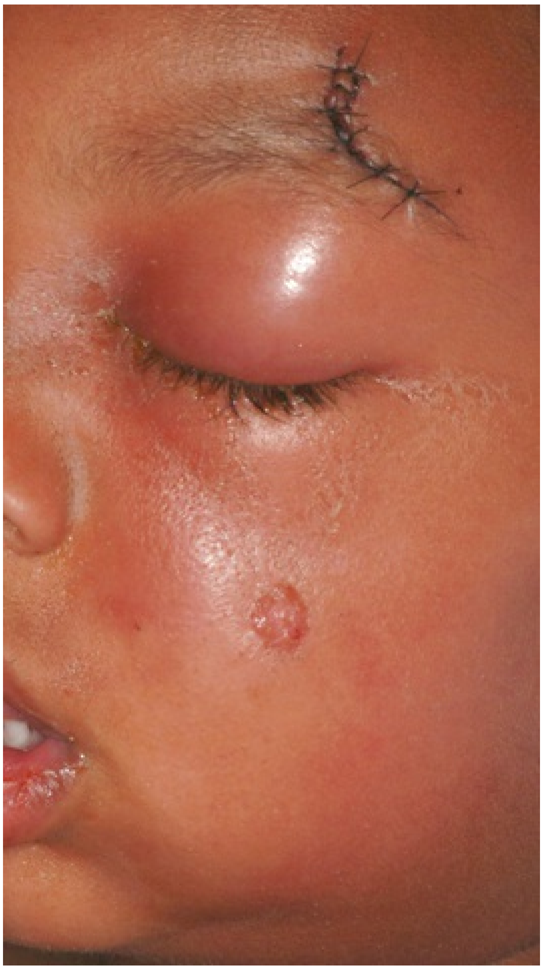

FIGURE 85.7 An infant with rapid onset of left eyelid swelling and erythema after a small laceration above the eye was sutured. Group A *Streptococcus* was recovered from the wound. (Courtesy of J. H. Briené.)

Several less common causes of lid cellulitis have been reported. Periocular cellulitis and abscess formation have resulted from infection with *P. multocida* in a healthy child who sustained a cat bite and cat scratch to the eyelid.[24] Ringworm (caused by *Trichophyton* spp.) also has been recognized as a cause of lid infection (leading to preseptal cellulitis) characterized by redness, swelling, ulceration, and vesicle formation.[25,26] A case of palpebral myiasis was reported in which larvae were extracted from a small draining fistula at the site of an erythematous and edematous lid.[27] Several cases of cellulitis of the eyelid due to *Bacillus anthracis* have been reported from Turkey.[28] The diagnosis was suspected when the erythematous and swollen lid developed an eschar. Scrapings showed the presence of gram-positive bacilli, which were confirmed by culture. A primary case of lymphocutaneous *Nocardia* *brasiliensis* of the eyelid has been reported in an adult hunting in England 2 weeks before presentation after a small abrasion on his lower eyelid.[29] In endemic countries, *Mycobacterium tuberculosis* should also be considered in patients who present with a swollen lid; in pediatric cases of tuberculous lesions of the eyelids, presentation usually is relatively indolent (2 days to 2 months), and intermittently draining cutaneous sinuses occur during the course of conventional antibiotic treatment for more typical bacterial disease.[30] Diagnosis is confirmed by a positive tuberculin skin test, the identification of a primary focus of tuberculosis in lung or bone, and response to antituberculous therapy. Intraorbital complications of mycobacterial infection also can occur.[31]

Patients with bacterial cellulitis of traumatized areas rarely have bacteremia. Precise bacteriologic diagnosis is made through culture of exudate from the wound. If there is no drainage, a careful attempt at tissue aspiration is undertaken if this can be done safely (i.e., at a distance far enough from the orbit that there can be no potential damage to the eye). A tuberculin syringe with a 25-gauge needle can be used for aspiration of "tissue juice." Usually, only a minuscule amount of infected material can be aspirated. A small volume of nonbacteriostatic saline (0.2 mL) is drawn into the syringe before the procedure. The saline is not injected into the skin; instead, it is used to expel the small volume of tissue fluid within the needle onto chocolate agar for culture.[32] Parenteral treatment similar to that for dacryocystitis is recommended in patients with bacterial cellulitis (unless an unexpected microbial etiology emerges), to hasten resolution and avoid spread of infection to the cavernous sinus.

Bacteremic Periorbital Cellulitis

Bacteremia as the pathogenetic mechanism of periorbital cellulitis has been very uncommon since the introduction of conjugate vaccines for *H. influenzae* type b (Hib) and *S. pneumoniae* (pneumococcal conjugate vaccine 7 [PCV7] and 13 [PCV13]) in 2000 and 2010, respectively.[33] In these cases, the child with bacteremic periorbital cellulitis, which most often is seen in infants younger than 18 months, has had a viral URI for several days. There is a sudden increase in temperature (to >39°C) accompanied by the acute onset and rapid progression of eyelid swelling. Swelling usually begins in the inner canthus of the upper and lower eyelid and can obscure the eyeball within 12 hours. Periorbital tissues are markedly discolored and usually erythematous, although if the swelling has been rapidly progressive, the area may have a violaceous discoloration.[34,35] The child's resistance to examination commonly leads to the erroneous impression of tenderness. Retraction or separation of the lids reveals that the globe is normally placed and extraocular eye movements are intact. If retraction of the lids is not possible, computed tomography of the orbit may be necessary.[36] The young age, high fever, and rapid progression of findings differentiate bacteremic preseptal cellulitis from other causes of swelling around the eye.

A precise bacteriologic diagnosis is made by recovery of the organism from blood culture. If a careful tissue aspiration is performed, culture of the specimen may have a positive result.

The pathogenesis of most of these infections, which usually occur during the course of a viral URI, is hematogenous dissemination from a portal of entry in the nasopharynx. This process is akin to the mechanism of most infections caused by Hib and some infections caused by *S. pneumoniae.*

In patients with bacteremic periorbital cellulitis, radiographs of the paranasal sinuses often are abnormal. However, the abnormalities almost certainly reflect the viral respiratory syndrome that precedes and probably predisposes to the bacteremic event, rather than a clinically significant sinusitis.[7] Bacteremic cellulitis rarely arises from the paranasal sinus cavities, as evidenced by the finding that typable *H. influenzae* organisms are almost never recovered from maxillary sinus aspirates and likewise are rarely recovered from abscess material in patients who have serious local complications of paranasal sinus disease, such as subperiosteal abscess. Although *S. pneumoniae* can cause subperiosteal abscess in patients with acute sinusitis, such patients usually are not bacteremic.

Treatment of suspected bacteremic periorbital cellulitis requires parenteral therapy. *S. pneumoniae* is the most likely cause in a child who has received both the Hib and PCV series. Because this infection usually is bacteremic in the age group in whom the meninges are susceptible to inoculation, it may be prudent to use an advanced-generation cephalosporin such as ceftazidime or ceftriaxone (150 or 100 mg/kg/day, respectively, divided into doses every 8 or 12 hours, respectively). Lumbar puncture should be performed unless the clinical picture precludes meningitis. Addition of vancomycin (60 mg/kg/day divided into doses every 6 hours) or rifampin (20 mg/kg once daily, not to exceed 600 mg/day) is appropriate if cerebrospinal fluid pleocytosis is present. When evidence of local infection has resolved and there is no meningitis, oral antimicrobial therapy is prescribed to complete a 10-day course.

Preseptal Cellulitis Caused by Inflammatory Edema of Sinusitis

Several complications of paranasal sinusitis can result in the development of swelling around the eye. The most common and least serious complication often is referred to as *inflammatory edema* or a *sympathetic effusion*.[6] This is a form of preseptal cellulitis, although infection is confined to the sinuses.

Typically, a child at least 2 years old has had a viral URI for several days when swelling is noted. Often, there is a history of intermittent early-morning periorbital swelling that resolves after a few hours. On the day of presentation, the eyelid swelling does not resolve typically but progresses gradually (see Fig. 85.1). Surprisingly, striking degrees of erythema also can be present. Eye pain and tenderness are variable. Eyelids can be very swollen and difficult to evert, requiring the assistance of an ophthalmologist. However, there is no displacement of the globe or impairment of extraocular eye movements. Fever, if present, is usually of low grade.

The peripheral white blood cell count is unremarkable, blood culture is sterile, and if a tissue aspiration is performed, culture is sterile. Sinus radiographs or other images show ipsilateral ethmoiditis or pansinusitis. The age of the child, gradual evolution of lid swelling, and modest fever differentiate inflammatory edema from bacteremic periorbital cellulitis.

The pathogenesis of sympathetic effusion or inflammatory edema is attributable to the venous drainage of the eyelid and surrounding structures. The inferior and superior ophthalmic veins, which drain the lower lid and upper lid, respectively, pass through or just next to the ethmoid sinus. When the ethmoid sinuses are completely congested, physical impedance of venous drainage occurs, resulting in soft tissue swelling of the eyelids, maximum at the medial aspect of the lids. In this instance, infection is confined within the paranasal sinuses. The globe is not displaced, and there is no impairment of the extraocular muscle movements. However, inflammatory edema is part of a continuum, with more serious complications resulting from the spread of infection outside the paranasal sinuses into the orbit.[37] Rarely, infection progresses despite initial optimal management of sympathetic effusions.

The infecting organisms in cases of inflammatory edema are the same as those that cause uncomplicated acute sinusitis (i.e., *S. pneumoniae,* nontypable *H. influenzae,* and *Moraxella catarrhalis*). Antibiotic therapy can be given orally if, at the time of the first examination, the eyelid swelling is modest (lid closure <50%), the child does not appear toxic, and the parents will adhere to management. Otherwise, admission to the hospital and parenteral treatment should be undertaken.

The only source of bacteriologic information is that obtainable by maxillary sinus aspiration, which is not usually performed. Appropriate agents for outpatient therapy should have activity against β-lactamase−producing organisms (e.g., amoxicillin −potassium clavulanate, cefuroxime axetil, and cefpodoxime proxetil). Parenteral agents include ceftriaxone (75 to 100 mg/kg/day, given as a single dose) or ampicillin-sulbactam (200 mg/kg/day divided into doses every 6 hours). The latter combination, although not approved for children younger than 12 years, is an attractive choice. Although the use of topically applied intranasal decongestants such as oxymetazoline has not been evaluated systematically, such agents may be helpful during the first 48 hours. After several days, when the affected eye has returned to near normal, an oral antimicrobial agent is substituted to complete a 14-day course of therapy.

A handful of children who present with a swollen eye experience one or more recurrences. In these cases anatomic abnormalities must be considered (natural or acquired bony dehiscences in the lamina papyracea,[38] or uncinate process[39]) in addition to reactivation of herpes simplex virus infection, sinusitis, allergic inflammation,[40] and orbital cysts derived from lacrimal tissue.[41]

Orbital Infection

The child or adolescent with true orbital disease secondary to sinusitis usually has sudden onset of erythema and swelling about the eye after several days of a viral URI (Fig. 85.8). Eye pain can precede swelling and often is dramatic. The presence of fever, systemic signs, and toxicity is variable. Orbital infection is suggested by proptosis (with the globe usually displaced anteriorly and downward), impairment of extraocular eye movements (most often upward gaze), or loss of visual acuity or chemosis (edema of the bulbar conjunctiva). Although most cases of orbital cellulitis secondary to sinusitis originate as a complication of viral URI, a few cases are of odontogenic origin.[42,43] Rarely, orbital abscess can occur without apparent underlying sinus or dental disease and absent acute signs of infection.[44] Fortunately, orbital infection is the least common cause of the "swollen eye."

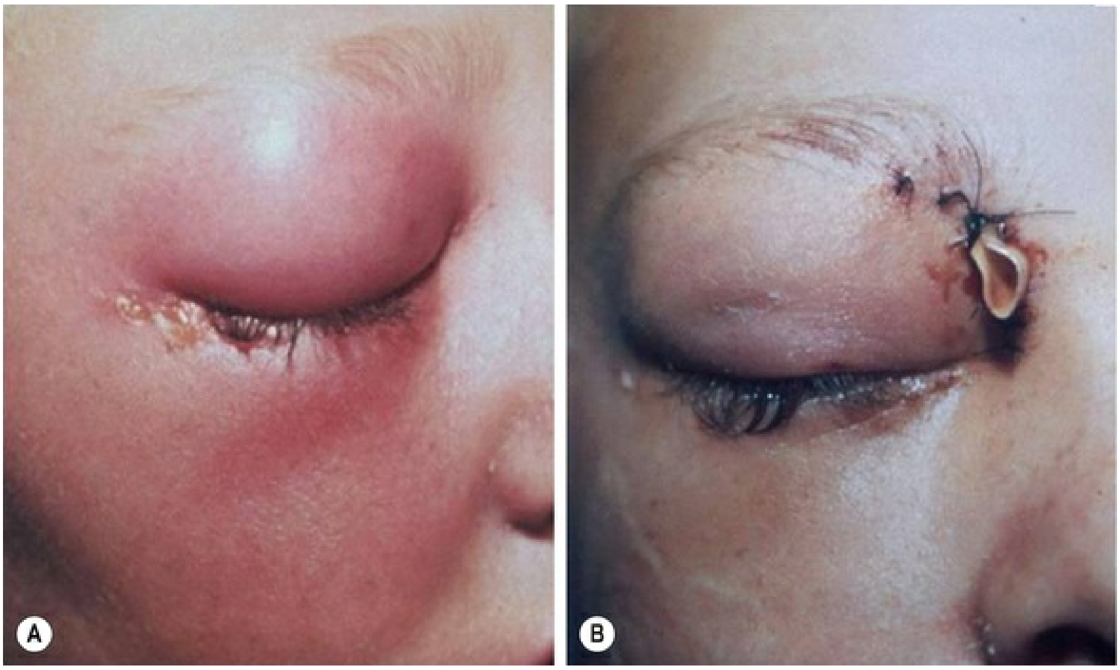

FIGURE 85.8 A boy with orbital cellulitis complicating sinusitis, before (A) and after (B) drainage. He had a 3-day history of eye pain with progressive swelling and erythema of the eyelids. He had proptosis, chemosis, and upward gaze palsy. (Courtesy of J. H. Briené.)

Most orbital infections involve the formation of a subperiosteal abscess. In young children, such an abscess results from ethmoiditis and ethmoid osteitis. In the adolescent, subperiosteal abscess can be a complication of frontal sinusitis and osteitis. Rarely, orbital cellulitis evolves, without formation of subperiosteal abscess, by direct spread from the ethmoid sinus to the orbit through natural bony dehiscences in the bones that form the medial wall of the orbit.

In addition to proptosis, impaired extraocular movements and loss of visual acuity, other factors, including age, extent of periorbital edema, absolute neutrophil count (>10,000/mm^3), and previous antibiotic treatment, may be used to estimate risk for orbital infection.[45] Imaging studies usually are performed if orbital disease is suspected to help determine whether subperiosteal abscess, orbital abscess, or orbital cellulitis is the cause of the clinical findings (Fig. 85.9).[46] In the presence of a large, well-defined abscess, complete ophthalmoplegia, or impairment of vision, prompt operative drainage of the paranasal sinuses and the abscess is performed.[47,48] Additional criteria include superior or inferior subperiosteal abscess, intracranial spread, frontal sinus involvement, and age greater than 9 years.[49] Subperiosteal abscess frequently can be drained successfully by endoscopy performed through an intranasal approach, thus avoiding an external incision.[50–52] In many cases, inflammatory tissue, rather than a well-defined abscess, is observed interposed between the lateral border of the ethmoid sinus and the swollen medial rectus muscle. Antimicrobial therapy alone usually is successful in such patients, as well as in patients with small abscesses that responded rapidly.[47,53–55] If the patient and ocular findings do not improve after 24 to 48 hours, surgical intervention is appropriate. Occasionally, computed tomography can suggest an abscess when only inflammatory edema is present[37,56]; accordingly, the clinical course is the ultimate guide to management.

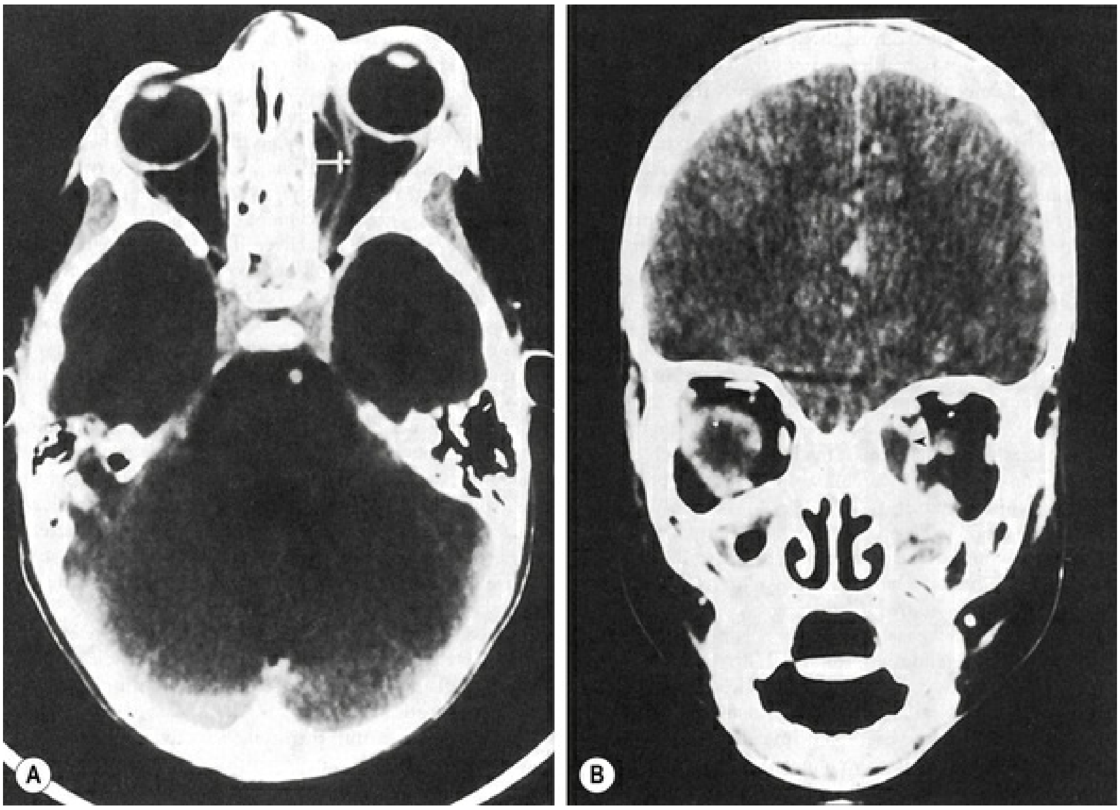

FIGURE 85.9 Axial (A) and coronal (B) computed tomography scans show a subperiosteal abscess extending from the left ethmoid sinus.

Empiric antimicrobial therapy should be chosen to provide activity against *S. aureus, S. pyogenes, Streptococcus anginosus,* and anaerobic bacteria of the upper respiratory tract (anaerobic cocci, *Bacteroides* spp., *Prevotella* spp., *Fusobacterium* spp., and *Veillonella* spp.) in addition to the usual pathogens associated with acute sinusitis (i.e., *S. pneumoniae, H. influenzae,* and *M. catarrhalis*).[49,57,58] An appropriate regimen is ampicillin-sulbactam (200 mg/kg/day divided into doses every 6 hours) plus vancomycin (60 mg/kg/day in 4 divided doses). Vancomycin will provide coverage in the event the causative organism is MRSA or if *S. pneumoniae* is highly resistant to penicillin. If surgery is performed, Gram stain of material drained from the sinuses or the abscess guides consideration of additional drugs or an altered regimen. When final results of culture and susceptibility tests are available, antibiotic therapy may be adjusted if necessary. Intravenous therapy is maintained until the eye appears nearly normal. At that time, oral antibiotic therapy can be substituted to complete a 3-week course of treatment.

Infection Following Trauma

Sarah L. Wingerter

Trauma is a major cause of morbidity in children and is the leading cause of death in children older than 1 year. About 90% of childhood injuries are secondary to blunt trauma, often caused by motor vehicle crashes, falls, or abuse.[1,2] Infection that follows trauma can be due to the injury itself or, more commonly, can be a consequence of healthcare procedures and prolonged hospitalization. In one study, 10% of children admitted to a pediatric intensive care unit after trauma experienced infection.[3] The incidence of infection following trauma in adults may be as high as 25%; wound infections or other hospital-associated infections appear to be equally likely.[3] Hospital-associated infections are addressed in detail in Chapter 99. Trauma-associated infections, which can cause considerable morbidity, are the focus of this chapter.

Pathogenesis

Severe injuries increase a child's susceptibility to infection for several reasons. Breaks in the skin and mucosal barriers allow pathogens to gain entry, and accumulation of blood provides a favorable environment for bacterial growth. Devitalized or necrotic tissue at the injury site can harbor pathogens that can evade the host's defense mechanisms. Foreign bodies introduced by the injury itself or as a consequence of hospitalization (e.g., catheters) allow entry and persistence of pathogens. Risk factors for infection in patients hospitalized for trauma include the severity of the injury, the presence of shock, the number of organs injured, and the amount of blood lost.[4,5] Other potential risk factors are underlying host factors and the number and virulence of organisms introduced as a result of injury.

Trauma can adversely affect host defense mechanisms. Monocyte activation occurs rapidly after severe injury and hemorrhagic shock. After monocyte activation, inflammatory mediators can be released in a dysregulated pattern, leading to the systemic inflammatory response syndrome[6] (see Chapter 11). Complement is activated by injured tissue, thus decreasing complement levels, and antibody production also diminishes after blunt trauma.[7] Suboptimal nutrition can further impair immune responsiveness.

General Principles of Management

Patients who sustain trauma can exhibit signs and symptoms consistent with infection in the absence of infection. Retroperitoneal blood can cause fever, as can atelectasis. Pulmonary contusions can mimic pneumonia radiographically, and the signs and symptoms of hemorrhagic shock can be indistinguishable from those of septic shock. Thorough evaluation may be hampered by a patient's immobility or diminished neurologic status and by dressings that can obscure foci of infection. The decision to begin antibiotic therapy should be made carefully, after acquisition of appropriate microbiologic specimens. Appropriate use of antibiotics can benefit the patient, but inappropriate use has no benefit and can lead to adverse effects and promote the development of resistant organisms.

Measures to reduce infection include rapid surgical intervention when necessary, removal of unnecessary catheters, and strict attention to infection-control procedures and hand hygiene. Prophylactic or presumptive antibiotic therapy may be beneficial in some circumstances.

Immunity to tetanus should be assessed in any patient with an open wound. Tetanus toxoid-containing vaccine should be given to any child in whom the primary vaccination series has been delayed or who has not received tetanus vaccine in more than 5 years. Tetanus immune globulin should be used in conjunction with the vaccine in high-risk wounds (e.g., puncture wounds, wounds contaminated with soil, feces, or saliva) if the child has not received adequate prior immunization. Children 11 to 18 years old who were vaccinated against tetanus 5 years earlier and require a tetanus toxoid–containing vaccine as part of wound management should receive a tetanus toxoid, reduced diphtheria toxoid, acellular pertussis vaccine (Tdap) if they have not received Tdap previously.[8]

The use of prophylactic or presumptive antibiotic therapy in select situations can reduce the incidence of infection (Table 86.1); however, continuation of antibiotic therapy longer than 24 hours has not demonstrated additional benefit, as discussed in detail later.

TABLE 86.1

Common Pathogens and Recommended Prophylaxis Following Trauma

Type of Trauma	Common or Important Pathogens	Recommended Prophylaxis
All trauma	*Clostridium tetani*	Ensure tetanus immunity or give vaccine ± tetanus immune globulin
Penetrating abdominal injuries	Enteric gram-negative bacilli and anaerobic bacteria	Ceftriaxone plus metronidazole, or cefoxitin, or gentamicin plus metronidazole
Splenectomy	Encapsulated organisms, e.g., *Streptococcus pneumoniae, Haemophilus influenzae,* and *Neisseria* spp.	Ensure vaccination against all three organisms. Give penicillin prophylaxis
Basilar skull fracture	Meningitis due to respiratory tract organisms	No prophylaxis recommended
Open fractures (including skull)	*Staphylococcus aureus,* gram-negative bacilli	Nafcillin, or cefazolin, or clindamycin.[a] Add gram-negative coverage for grade III fractures
Thoracic trauma requiring chest tube	*S. aureus* and *Streptococcus* spp.	Nafcillin, or cefazolin, or clindamycin[a]

[a] Vancomycin may be appropriate if methicillin-resistant *S. aureus* (MRSA) is prevalent in the community or if the patient is known to be colonized with clindamycin-resistant MRSA.

Nutritional status also can affect infection risk. Patients with trauma who are given enteral nutrition have a lower risk for infectious complications than those given intravenous nutrition.[9,10]

There is conflicting evidence on whether injured patients fed an enteral diet rich in glutamine, arginine, and omega-3 fatty acids have a lower risk for infection than those fed a standard enteral diet or those who receive no early enteral nutrition.[11–13]

Skin and Soft Tissue Trauma

Factors associated with a greater risk for infection after injury to the skin and soft tissues are the severity of the wound, shock, and blood loss (Table 86.2).[4,7] Because wounds sustained in trauma are inherently contaminated, thorough cleansing and debridement of devitalized tissue have preeminent importance in preventing infection.

TABLE 86.2

Infection Risk and Management Following Trauma

Type of Trauma	Infection Risk	Intervention
Skin and soft tissue	*Streptococcus pyogenes* (GAS) <2 days Methicillin-susceptible/methicillin-resistant *Staphylococcus aureus* (MSSA/MRSA) ≥2 days	First-generation cephalosporin; wound culture; consider other antibiotics based on local resistance patterns (clindamycin, TMP-SMX, tetracycline, rifampin); vancomycin or linezolid if life-threatening
Animal/human bites	As above, plus *Pasteurella multocida, Eikenella corrodens,* anaerobic bacteria	Blood culture, needle aspirate; β-lactam/β-lactamase inhibitor agent, clindamycin plus TMP-SMX if penicillin-allergic
Body piercings, tattoos	Skin flora, *Pseudomonas aeruginosa*	Ceftazidime or piperacillin-tazobactam
Water associated		
Fresh water	*Aeromonas hydrophila*	Third- or fourth-generation cephalosporin or extended-spectrum β-lactam
Salt water or contact	*Vibrio vulnificus*	Third-generation cephalosporin with raw seafood exposure
Fish spines, fish tanks	*Mycobacterium marinum*	Surgical excision; combination antibacterial therapy
Blunt/penetrating trauma		
Pyomyositis	*S. aureus*, GAS	Surgical drainage, debridement; antibiotics
Necrotizing fasciitis/gas gangrene	*S. aureus*, GAS, *Clostridium* species	Fasciotomy; debridement; penicillin or nafcillin plus clindamycin (consider vancomycin)
Abdominal trauma		
Penetrating: higher risk for intestinal injury + spillage of bowel contents	Acute: peritonitis (±septicemia) Later: abscess, surgical	Surgical exploration, metronidazole plus aminoglycoside (see text)

Blunt: risk for duodenal/pancreatic hematoma (increased risk for infection if large-volume transfusion required)		Aminoglycoside or third-generation cephalosporin; surgical/CT-guided abscess drainage site of infection
Splenic rupture:		
Nonoperative	Blood transfusions pathogens	
Splenectomy	Postsplenectomy septicemia (encapsulated organisms)	Immunizations: Hib, pneumococcal, meningococcal vaccines; penicillin prophylaxis until at least 5 years of age and 1 year after splenectomy
Head trauma	Meningitis (especially with basilar skull fracture, penetrating trauma, or open wounds); ventriculitis; brain abscess, *S. pneumoniae, H. influenzae, N. meningitidis,* GAS, *S. aureus,* gram-negative bacilli	CSF analysis and culture; antibiotics with good CSF penetration; gram-positive coverage, e.g., vancomycin plus third-generation cephalosporin; gram-negative coverage if contaminated wound or extensive soft tissue damage; surgical intervention if persistent CSF leak
Fractures		
Open	Highest risk: grade IIIB or IIIC, internal/external fixation device, involvement of lower leg; *S. aureus, Enterobacter* spp., *Pseudomonas* spp.	Surgical debridement; antibiotic therapy. Antibiotic prophylaxis for open fractures: gram-positive coverage for open fractures; gram-negative coverage for grade III; add high-dose penicillin if fecal contamination or clostridial infection suspected clinically
Puncture wounds of the foot	Cellulitis, abscess, osteochondritis; *Pseudomonas* spp., *S. aureus,* GAS, *E. corrodens* (toothpick)	Surgical debridement; antibiotics
Thoracic trauma		
Pulmonary contusion, hemothorax, pneumothorax	Risk factors for hospital-associated pneumonia: prolonged intubation, poor pulmonary toilet, aspiration	Antibiotics active to cover oropharyngeal/nasopharyngeal organisms (including anaerobes) and defined gram-negative bacilli by local intensive care unit pathogens and respiratory culture. Empiric choices: clindamycin plus third-generation cephalosporin or aminoglycoside; or β-lactam/β-lactamase inhibitor

CSF, cerebrospinal fluid; CT, computed tomography; GAS, group A *Streptococcus;* Hib, *Haemophilus influenzae* type B; TMP-SMX, trimethoprim-sulfamethoxazole.

Cellulitis can follow minor or major trauma to the skin. Rapidly spreading cellulitis that occurs within 2 days of injury is more likely due to *Streptococcus pyogenes* (group A *Streptococcus* [GAS]), whereas staphylococcal cellulitis may not manifest for several days. Although GAS and *Staphylococcus aureus* are the most common causes of cellulitis, other pathogens should be considered in certain settings. Animal or human bites can lead to infection with

Pasteurella multocida or *Eikenella corrodens,* respectively, as well as with anaerobes, *S. aureus,* and GAS. Body piercings and tattoos, which are increasingly common in adolescents, also can lead to bacterial infection. Although skin flora usually is the cause, *Pseudomonas aeruginosa* is a common cause of infection following piercing of the auricular cartilage,[14] and there have been outbreaks of methicillin-resistant *S. aureus* (MRSA) infections in tattoo recipients.[15] Hepatitis B, hepatitis C, and human immunodeficiency virus (HIV) infection also can be transmitted through piercing and tattooing. *Aeromonas hydrophila* infection is associated with lacerations obtained while swimming in fresh water, and *Vibrio vulnificus* can cause skin or soft tissue wound infections after contact with salt water or drippings from raw seafood. *Mycobacterium marinum* can cause cutaneous infection after freshwater or salt-water injuries from fish spines or marine shellfish, or from contamination during exposure to fishtanks.[16]

Culture of blood and needle aspirate specimens have low yield in typical cases of cellulitis but can be revealing in cases of cellulitis associated with animal bites or other unusual injuries.

For mild to moderate cases of typical wound cellulitis, empiric therapy with a first-generation cephalosporin provides coverage for the most common pathogens, including *S. aureus* and GAS. The emergence of community-associated MRSA (CA-MRSA) in posttraumatic skin and soft tissue infections makes empiric treatment problematic.[17,18] Children colonized with MRSA have a greater risk for developing a wound infection after trauma. For more severe cases of cellulitis, for wound infections requiring hospitalization, or for an infection not responding to initial β-lactam antibiotic therapy, a diagnostic specimen should be obtained and treatment should include coverage of MRSA.[19] Although many CA-MRSA are susceptible to clindamycin,[20,21] some have inducible or constitutive clindamycin resistance.[22,23] Most strains also are susceptible to tetracycline (which should be avoided in children <9 years), trimethoprim-sulfamethoxazole, and rifampin. For life-threatening infections possibly due to MRSA, appropriate therapy would include vancomycin or linezolid.[24] Knowledge of local antibiotic resistance patterns should guide empiric therapy.[25]

Pyomyositis can occur after blunt or penetrating trauma and usually is caused by *S. aureus* or GAS. Treatment involves surgical drainage, debridement, and antibiotic therapy. Necrotizing fasciitis, due to GAS or *S. aureus,* and gas gangrene, usually due to *Clostridium* spp., can complicate traumatic wounds and are surgical emergencies. A characteristic symptom is intense pain, often out of proportion to findings on examination, which can include discoloration of the overlying skin, swelling, and crepitus. Patients with necrotizing fasciitis also can have concomitant toxic shock syndrome. Computed tomography (CT) or magnetic resonance imaging may show muscle swelling, fluid collections, or, in the case of gangrene, gas in the muscle. Leukocytosis, thrombocytopenia, a rising creatine kinase level, and hypocalcemia can be seen in these patients.

Therapy for necrotizing fasciitis involves immediate surgical fasciotomy and debridement. Penicillin or nafcillin plus clindamycin should be given for streptococcal and clostridial infections.[26,27] Although penicillin G is the drug of choice for invasive GAS infections, clindamycin also should be used for deep infections such as necrotizing fasciitis. In a mouse model of streptococcal myositis, clindamycin was found to be superior to penicillin.[28,29] The likely explanation is that the high density of GAS leads to reduced replication and decreased expression of penicillin-binding proteins.[29] Clindamycin, which inhibits protein synthesis, maintains its activity against these slowly replicating bacteria and also inhibits the production of bacterial toxins. Clindamycin should not be used alone until results of susceptibility testing are available because some GAS organisms are resistant.

Abdominal Trauma

Trauma to the abdomen can be blunt or penetrating. Penetrating trauma is less common but carries a higher risk for intestinal injury. Either penetrating or blunt trauma can cause intestinal tears that lead to spillage of bowel contents into the peritoneum. Injuries to the colon are associated with a higher risk for infection because of the higher density of organisms in the more distal bowel.[30] Blunt trauma related to physical abuse can cause hematoma of the duodenum and pancreatitis. Requirement for a large volume of transfusion is also a risk factor for infection after abdominal trauma.[5]

Infection can manifest acutely as peritonitis, with or without septicemia, or later, as an abscess or surgical site infection. Diagnosis is aided by CT or, in a patient who cannot be moved, ultrasonography. Needle aspiration of peritoneal fluid is performed in patients with peritonitis to confirm the diagnosis and establish the etiology. Treatment of an established infection requires empiric therapy with antibiotics effective against gram-negative and anaerobic bacteria, and surgical or CT-guided drainage if an abscess is present. Appropriate choices are metronidazole plus an aminoglycoside or third-generation cephalosporin, or piperacillin-tazobactam. It is not clear that empiric therapy with antienterococcal agents improves outcome in these patients; however, antienterococcal therapy should be considered for children who have persistent symptoms or when *Enterococcus* is isolated from peritoneal fluid cultures.

Surgical exploration is part of the routine management of penetrating abdominal injuries, and antibiotic therapy should be started as soon as possible. Fullen and associates[31] showed that patients with penetrating abdominal injuries who received antibiotics before surgery had a lower incidence of infection than patients who received the first dose of antibiotics intraoperatively or postoperatively. Because patients with penetrating abdominal injuries are presumed to have bacterial contamination of the peritoneum at the time of injury, antibiotic therapy should be considered as preemptive therapy.

The empiric antibiotic regimen should include agents effective against gram-negative enteric and anaerobic bacteria, which play a critical role in intra-abdominal infections after injury.[32] Single-drug therapy with a second-generation cephalosporin, such as cefoxitin or piperacillin-tazobactam, appears to be as effective as traditional three-drug antibiotic regimens in preventing infection in adults with penetrating abdominal injuries; resistance of anaerobic bacteria to cefoxitin and stimulation of production of extended-spectrum β-lactamases limit current use.[33,34] Other appropriate therapies include a third-generation cephalosporin plus metronidazole or an aminoglycoside plus metronidazole. Patients with trauma have a higher volume of drug distribution, so higher doses of aminoglycosides may be needed.[35,36]

Several studies have evaluated the appropriate length of presumptive therapy for patients with penetrating abdominal injuries. No significant difference in infection rate was found between patients treated for 24 hours and those treated for 5 days.[30,34,37–39] Therefore, current evidence does not support the use of antibiotics beyond 24 hours in patients with penetrating abdominal injuries, even if they have colonic injuries. Longer duration of antibiotic therapy promotes bacterial resistance and fungal overgrowth and may lead to additional side effects without further reducing the likelihood of infection.[40]

Splenic rupture after trauma deserves special consideration (see Chapter 106). If the rupture is managed nonoperatively, multiple blood transfusions may be required, placing the patient at risk for bloodborne pathogens. If splenectomy is performed, the child is at risk for overwhelming postsplenectomy septicemia, especially due to encapsulated organisms. The risk for septicemia in a child who has undergone traumatic splenectomy is as much as 350 times higher than that in a healthy child. Younger children are at higher risk for septicemia than older children. Although the period of greatest risk appears to be the first 2 years after splenectomy, septicemia has been reported up to 25 years after splenectomy. Therefore, observation or splenic repair is preferred if the child is clinically stable.[41,42]

If splenectomy is performed, immunizations should be reviewed to ensure that the child has been appropriately immunized with the *Haemophilus influenzae* type b and pneumococcal conjugate vaccines. Children 2 years and older who have been adequately immunized with the 13-valent pneumococcal conjugate vaccine (PCV13) should be given a dose of the 23-valent polysaccharide vaccine (PPSV23). They should receive a second PPSV23 dose 5 years after the first. Children 24 through 71 months of age who are fully immunized with PCV7 should receive one dose of the PCV13 as well as a dose of the PPSV23 at least 8 weeks later and then again 5 years later. Children 6 through 18 years of age also should receive the PCV13 and PPSV23 on a similar schedule (see Chapter 123 for additional circumstances). In addition, penicillin prophylaxis is recommended for children younger than 5 years and also for at least 1 year after trauma-related splenectomy in older children.[41] Meningococcal conjugate vaccine (ACWY or CY) should be administered to children 2 months and older (avoiding use of one product, MCV4-

D, Menactra, until 2 years of age or after completion of all indicated pneumococcal conjugate vaccines). Booster doses are required throughout life (see Chapter 125). Meningococcal B vaccine is indicated as a 2-dose (MenB-4C) or 3-dose (MenB-FHbp) series for those 10 years and older.[43]

Head Trauma

Head trauma is common in children, and central nervous system injury increases mortality among injured children.[1] As many as one half of patients with head trauma develop an infectious complication, most often a hospital-associated infection.[44] Trauma-related infectious complications include meningitis, ventriculitis, and brain abscess; common pathogens are *Streptococcus pneumoniae* and other upper respiratory tract organisms such as *H. influenzae, Neisseria meningitidis,* and GAS. Staphylococcal and gram-negative bacillary meningitis can occur after penetrating trauma, with open wounds, or postoperatively or can be associated with devices or occur after prolonged hospitalization.[45] It is essential to obtain cerebrospinal fluid (CSF) for culture if the diagnosis of meningitis is being considered after head trauma; CSF cell count as well as glucose and protein level can be difficult to interpret in the presence of subarachnoid hemorrhage. Treatment includes antibiotic therapy as well as possible surgical intervention in patients with device in place or after persistent CSF leakage.

Basilar skull fracture accounts for up to 20% of skull fractures and is associated with substantial risk for bacterial meningitis. Meningitis is a consequence of the communication created between the subarachnoid space and the colonized paranasal sinuses, nasopharynx, and middle ear. After basilar skull fracture, the incidence of meningitis can be as high as 17% and approaches 50% in patients who also have a CSF leak. However, a 1998 meta-analysis of 12 studies involving 1241 patients with basilar skull fractures suggested that antibiotic prophylaxis did not prevent meningitis.[46] Even when children and patients with CSF leakage were analyzed separately, there was no evidence that antibiotic prophylaxis decreased the risk for meningitis. In addition, the rate of meningitis in children after basilar skull fracture was only 3%, much lower than rates reported in adults. A 2006 Cochrane

Database review found that antibiotic prophylaxis had no significant effect on reducing the frequency of meningitis, all-cause mortality, or meningitis-related mortality in patients with basilar skull fractures.[47] Available data therefore do not support the use of prophylactic antibiotics in children with basilar skull fractures.

Prophylactic antibiotics usually are given after an open skull fracture, although there are few data to guide recommendations. Antibiotics chosen should have good CSF penetration and cover gram-positive organisms. Coverage for gram-negative organisms may be needed if the wound is heavily contaminated or there is extensive soft tissue damage.

Fractures

Fractures are common childhood injuries and can be either closed or open. Open fractures can be graded on a scale of I to III on the basis of wound size and amount of soft tissue damage. Grade III fractures are further subdivided (IIIA, IIIB, and IIIC) according to vascular injuries and soft tissue defects. Dellinger and colleagues,[48] evaluating factors associated with infection after open-extremity fractures, found the following independent risk factors: severity of fracture (grade IIIB or IIIC), the placement of an internal or external fixation device, and involvement of the lower leg. Organisms most commonly implicated in fracture-associated infections were *Staphylococcus* spp., *Enterobacter* spp., and *Pseudomonas* spp.[48–50] Therapy consists of surgical removal of infected tissue and antibiotics.

Infection rates associated with open fractures range from as high as 9% for grade I fractures to 50% for grade III fractures. Infection after open fracture can lead to delayed bone healing, prolonged hospitalization, and permanent disability. Open fractures have a higher risk for infection than closed fractures because bone and soft tissue contamination likely occurred at the time of injury.

Several studies have demonstrated a reduced risk for infection after open fractures in patients given prophylactic therapy with antibiotics effective against *S. aureus.*[51–53] In addition to *S. aureus,* gram-negative bacilli such as *Pseudomonas* and *Enterobacter* spp. can cause open-fracture–associated infections, especially with grade III fractures. The Eastern Association for the Surgery of Trauma

(EAST) guidelines revised in 2009 recommend the following: prophylactic antibiotics with gram-positive coverage as soon as possible after injury for all trauma with open fractures; additional coverage for gram-negative organisms for grade III fractures. For grade I and II fractures, antibiotics should be discontinued 24 hours after wound closure. Additionally, for grade III fractures, antibiotics should be continued for only 72 hours after the time of injury or not more than 24 hours after soft tissue coverage of the wound, whichever comes first. A Cochrane database review from 2010 also found evidence for benefit of antibiotic prophylaxis at the time of surgery for closed long-bone fractures.[54]

The use of antibiotic-impregnated beads, cement, and polymers has shown some promise in reducing open-fracture–associated infections.[50,52,55] Prospective randomized trials are needed to determine effectiveness.

Puncture Wounds

The management of infection after a puncture wound to the foot deserves special consideration. Up to 18% of such wounds are complicated by cellulitis or a soft tissue abscess, and up to 2% by osteochondritis. *P. aeruginosa* is responsible for as many as 90% of cases of osteochondritis after a puncture wound to the foot.[34] The liner of used sneakers has been found to contain *Pseudomonas,* making this a likely source; however, *Pseudomonas* can cause infection after a puncture wound through other shoes and even bare feet, and at other sites.[56] Other gram-negative bacilli, as well as *S. aureus* and GAS, also can cause osteochondritis after a puncture wound. *E. corrodens* and oral anaerobic bacteria have been reported after toothpick puncture injury to the foot.[57,58] Rarely, nontuberculous mycobacteria can be the primary pathogen.[59,60] Surgical debridement is the mainstay of management, both to obtain specimens for determining infectious etiology and to remove necrotic cartilage and any retained foreign body. After debridement, antipseudomonal therapy, if necessary, need only be continued for a week. Osteochondritis due to other organisms should be treated with a conventional course of therapy.

Thoracic Trauma

Thoracic injuries are a major cause of death in childhood trauma. Such injuries usually are blunt and often are due to a motor vehicle collision.[1] Significant chest trauma can lead to pulmonary contusion, hemothorax, and pneumothorax. Although any major trauma increases the risk for hospital-associated pneumonia due to prolonged intubation, poor pulmonary toilet, and the risk for aspiration, pulmonary contusions also lead to decreased pulmonary function, thereby further increasing the risk for pneumonia. The diagnosis of pneumonia can be challenging because fever and a pulmonary density can be due to the contusion itself. New onset of fever, leukocytosis, purulent secretions, and the need for increased ventilator settings are clues to the diagnosis. The antibiotic regimen for suspected pneumonia in this setting should take into account knowledge of the pathogens commonly identified in the local intensive care unit as well as results of culture of deep respiratory tract specimens, such as those collected by bronchoalveolar lavage when possible. Therapy consists of agents effective against defined oropharyngeal and nasopharyngeal or tracheal organisms, including anaerobic and gram-negative bacteria. Clindamycin plus either a third-generation cephalosporin or an aminoglycoside is appropriate, as is a β-lactam/β-lactamase–inhibiting agent.

Hemothorax due to blunt or penetrating thoracic trauma increases the risk for empyema, as does a thoracostomy tube placed to evacuate a hemothorax or pneumothorax. The risk increases with incomplete drainage of the pleural space or prolonged chest tube placement.[61] *S. aureus* and gram-negative bacilli predominate in these infections.[62] Prophylactic antibiotic therapy has been studied in the setting of tube thoracostomy after chest trauma. A meta-analysis of 9 prospective trials and 2 earlier meta-analyses found that prophylactic antibiotic therapy reduced the risk for subsequent pneumonia after thoracostomy tube placement.[63] A brief (24-hour) course of an antibiotic with good antistaphylococcal and antistreptococcal activity is appropriate after chest tube placement. Antibiotic prophylaxis for <24 hours also is recommended when open thoracotomy is performed for penetrating chest injury.[64]

Infection Following Burns

Jane M. Gould

In 2013, unintentional injury was the leading cause of death in children 1 to 18 years of age in the United States. Of these deaths, burns were the fifth leading cause in children younger than 1 year, the fourth leading cause in children 1 to 4 years of age, and the third leading cause in children 5 to 9 years old.[1] Overall, the nonfatal burn injury rate per 100,000 population in the age group of 1 to 19 years was 156.6 in 2013.[1] Children younger than 4 years and children with disabilities are at the greatest risk for burn-related death and injury.[2] Most of these injuries are preventable. Most young children suffer scald injuries from hot liquids or flame burns from house fires. Older children are more likely to sustain flame burns from accidents with flammable liquids or fireworks and from house fires. On occasion, burn injuries can result from medical therapies, such as therapeutic application of heat, ignition of flammable medications (rubbing alcohol and hot oils), or burns from hot-air vaporizers.[3] The latest comprehensive analysis, performed in 2006, revealed a total annual cost of scald burn-related deaths and injuries among US children ≤14 years of age of approximately $44 million, with children <4 years of age accounting for 90% of these costs. Total charges for pediatric admissions to burn centers average $22,700 per case.[2]

The survival of children with burns depends on the following factors: (1) age, (2) the percentage of total body surface area (TBSA) burned, (3) the depth of the burn injury, (4) the type of burn, and (5) management. Young children, particularly those <2 years, have a lower survival rate for the same TBSA burned than older children and adults. Advances in burn care (improvements in resuscitation, intensive care, and care of the burn wound) have narrowed the gap in survival for small children.[4] Currently, the extent of burn associated with a 50% survival in patients older than 1 year is TBSA of about 80%.[5] Data suggest that the most common causes of death in burned children are smoke inhalation and hypoxic-ischemic brain injury. The enormous progress in burn survival and therapy is attributable to the following factors: care of patients in centers specializing in the treatment of burns; knowledge of the pathophysiology of shock and aggressive treatment of patients with fluid resuscitation and other adjunctive therapies; recognition of the importance of the caloric requirement of the burned patient and its role in wound healing; and advances in the care of the burn wound itself, especially early debridement and excision of the wound, use of topical antimicrobial agents, judicious use of antibiotics systemically, and improved grafting materials and techniques.[6]

TBSA can be estimated either from the Lund and Browder chart or with use of the size of the patient's palm, which roughly is 1% of the TBSA at any age, as a measure.[7] Depth of burn injury is determined by the extent of damage to tissue and is classified by degrees: a first-degree burn involves the epidermis only and is painful, red, and dry, resembling a sunburn; a second-degree burn involves the dermis, is severely painful, usually is erythematous and is moist, weeps, and may have blisters and bullae; a third-degree burn involves the subcutaneous tissue and is usually white or waxy-appearing, dry, avascular, and painless. Depth is alternatively classified as either partial thickness, involving the epidermis or superficial dermis, or full thickness, involving the deep dermis and subcutaneous tissue. The larger the percentage of TBSA involved and the deeper the burn, the higher the mortality, both immediately after injury (primarily from shock or occasionally from other associated injuries) and after successful resuscitation (from infectious complications). The type of burn also is important; scald burn is less commonly fatal than flame burn, especially if the latter is associated with pulmonary injury.

Children with burns >30% TBSA, flame and inhalation injuries, and full-thickness burns are at highest risk for infectious complications.[8] Burn victims are susceptible to a wide variety of infections associated with relative immunosuppression and complications of intensive care. Virtually any organ can become the target of an infection in such patients. The most common infections in burned children are those related to the burn wound and catheter-associated septicemia.[8] Infections related to intravascular and urinary catheters and endotracheal tubes are discussed in Chapter 100. Infection of the burn wound occurs with greatest frequency in children.[9] Burn wound septicemia is associated with at least an 80% mortality rate in children.

Diagnosis of infectious complications in a burn victim is challenging. Although fever and elevated peripheral white blood cell count with a left shift are usual indicators of infection, their positive predictive value for diagnosis of infectious complications in burn victims is very low because they are commonly seen in uninfected burned children whose wounds are uncovered.[10] Neither severity of fever (frequently >39°C) nor response to antipyretic therapy is a reliable indicator of infection.[10] Peak fever in burned children without infection usually occurs on the second day after the burn, with a second peak around the sixth and seventh days.[11] Fever is probably the result of an increase in metabolic rate and an alteration of hypothalamic temperature regulation. Fever usually subsides without specific therapy, coincident with re-epithelialization of the burn wound or successful grafting of all open areas. Thus, fever alone in the burned child is not a reliable indicator of infection or of the need to investigate for infection or prescribe antibiotic therapy.

Hypothermia usually is a more reliable indicator of infection, although children with burns affecting a high percentage of TBSA who are left uncovered for prolonged periods during dressing changes can have hypothermia that requires external warming. Hypotension due to fluid shifts is common early in the postburn period and usually can be differentiated from infectious causes because of rapid improvement with fluid resuscitation.

Several inflammatory mediators have been evaluated in attempts to distinguish infection from the normal response to thermal injury. They include tumor necrosis factor-α (TNF-α),[12–14] interleukin=1β (IL-1β),[12,14] IL-6,[12,14] IL-8,[13,15] procalcitonin,[16,17] and C-reactive protein.[18] Levels of mediators in burned patients are higher than those in healthy children, probably owing to nonspecific inflammation associated with thermal injury. Although several studies have shown significant differences in levels of these inflammatory mediators between burned patients with septicemia and those with uncomplicated thermal injury,[12,13,15–17] none is highly discriminatory. However, changes in serial C-reactive protein levels can occur in septicemia an average of 2.3 days earlier than a decrease in platelet count or clinical manifestations.[18]

Thus diagnosis of infectious complications is made through evaluation of all clinical signs, examination of the burn wound and all catheter sites, and consideration of supporting laboratory evidence and results of culture of blood, urine, or quantitative burn wound biopsy specimens.

Burn Wound Infection

Burn wound infection is defined as the invasion of microorganisms into viable tissue under the wound. Local infection can result in prolonged wound healing or sloughing of graft, toxin production leading to distant organ damage, and septicemia and infection at distant sites.[19]

The diagnosis of burn wound infection is made from local signs of wound infection, with or without systemic signs indicating septicemia or toxemia (Box 87.1), in conjunction with histologic and microbiologic evidence of infection in biopsy specimens of burn wounds (Box 87.2). The technique for quantitative biopsy requires a 1-g specimen of eschar, which is homogenized and cultured.[20] The procedure consists of cleaning the open wound with alcohol and obtaining the specimen with a scalpel or a dermal punch. Processing of the biopsy consists of aseptic weighing, alcohol dip and flaming to remove surface contamination, dilution in fixed-volume thioglycolate broth or saline, homogenization, and inoculation onto nutrient agar.[21,22] Although selection of the biopsy site, retained activity of topical antimicrobial agents, and multistep processing can be sources of error, quantitative biopsy culture yielding growth of a single or multiple organisms, each with a density of $>10^5$ colony-forming units per gram of tissue, correlates with infection. Histologic diagnosis of infection is supported by the presence of bacteria invading viable tissue and can be obtained with frozen or permanent sections, the latter of which is thought to be more accurate.[20] Blood culture results are positive in only 40% to 50% of patients with burn wound sepsis.

Factors that influence burn wound infection pertain to the wound, the host, and the causative organisms.

Wound Factors

Skin is a primary, critical local defense mechanism against infection, providing a mechanical barrier to penetration of organisms that normally reside on the surface. Skin saprophytes are thought to inhibit colonization by more pathogenic bacteria. Skin also produces antibacterial substances, such as unsaturated free fatty acids, that inhibit a number of microorganisms, particularly group A *Streptococcus* (GAS).[23] Thermal injury rapidly disrupts normal functions and produces an ideal culture medium.

After burn injury, the wound site rapidly becomes colonized with normal skin flora and gram-positive pathogens, and then by endogenous or environmental gram-negative bacilli and fungi if the course is protracted. Isolation of microbes from a burn wound is not a priori evidence of infection because invasion into underlying viable tissue must occur for infection to develop.

Adequacy of blood supply to the wound is critical. Avascularity of the burned tissue results from coagulation of vessels and tissue that make a protein-rich eschar and renders the site inaccessible to systemic antibiotics as well as humoral and cellular defenses. Infection in the burn wound can extend into the blood vessels, causing thrombosis that can compromise the blood supply further, converting a partial-thickness burn into a full-thickness burn. Wound factors such as the acidic, anaerobic, moist environment of the avascular burn tissue favor growth of certain pathogens such as fungi and impair activity of aminoglycoside antibiotics. The cooler temperature of the burn wound may influence infection because lower temperatures restrict blood flow, possibly causing further tissue necrosis and impairing phagocytic cell metabolism.[24] In addition, the location of the wound can contribute to the overall risk for infection, as is seen with exposure of the globe, bones, cartilage, and joints.[20] Likewise, the presence of foreign bodies in the wound also can promote infection.

Host Factors

Several host factors have been identified that influence the likelihood of burn wound infection. Children with underlying medical conditions, such as diabetes mellitus, neurologic disorder, and immunodeficiency, are more likely to experience burn wound septicemia, resulting in very high mortality.

Immunologic dysfunction is well described in patients who sustain burn injuries of >30% TBSA, with degree correlating directly with TBSA burned (Table 87.1).[25–52] The mechanism is unknown. It has been suggested that immunosuppression after injury evolves to protect against autoimmunity that might otherwise result from antigenic bombardment after intense tissue injury.[42,53,54] Immunosuppression of burned patients greatly increases their susceptibility to infection. Polymorphisms in the genes that encode toll-like receptor 4 and TNF-α are significantly associated with increased risk for severe septicemia after burn trauma.[55]

TABLE 87.1

Immunologic Dysfunction in Burned Children

Type of Dysfunction	References
HUMORAL IMMUNE FUNCTION	
Decreased numbers of B lymphocytes	25–27
Decreased total immunoglobulins	27–35
Decreased fibronectin	26, 27, 36–38
Aberrant production of immunomodulators	24, 26, 28, 39, 40
CELLULAR IMMUNE FUNCTION	
Anergy	26, 27, 41
Decreased mitogen and antigen responses	26, 29, 42

Decreased macrophage and monocyte function	52
Complement-induced increase in release of immunosuppressive mediators	27

Causative Organisms

Organisms causing burn wound infection have changed during the past century. In the 1930s and 1940s, GAS was the predominant pathogen, followed by *Staphylococcus aureus.* In the 1950s and early 1960s, the predominant pathogen in such infections was *S. aureus.* Gram-negative bacilli, especially *Pseudomonas aeruginosa,* became the predominant pathogen in the 1960s and early 1970s. Since then, *S. aureus* has regained prominence (becoming the most common pathogen in many centers[8,56]), including methicillin-resistant *S. aureus* (MRSA), and the spectrum of gram-negative bacilli has broadened with increasing antimicrobial resistance.[57] Fungal and viral pathogens have become increasingly important. These changes are direct reflections of complications of aggressive therapy and survival of more severely affected patients.

The number of organisms present on the burn wound is an important factor in infectivity. It is theorized that high temperature initially sterilizes the burn wound. However, rapid colonization by normal skin flora and existent pathogens follows. At the time of hospitalization in our pediatric burn unit, routine cultures reveal that 9% and 54% of patients are colonized with GAS and *S. aureus*, respectively. Colonization of the wound surface is not equivalent to infection. Usually, a bacterial density of 10^5 organisms per gram of tissue is required before invasion of underlying viable tissue (burn wound infection) occurs. Infection can occur with lower bacterial densities, but rarely. The most common organisms to cause wound infections are *S. aureus* and *P. aeruginosa.*[20]

An organism's unique virulence, invasiveness, and motility also affect pathogenicity. It has been demonstrated that nonmotile strains of *Pseudomonas* spp. rarely cause infection.[58]

Early Infections

Colonization pattern of burn wounds is somewhat predictable over time. Initially, gram-positive organisms are present; infection that occurs in the first 48 hours after the burn usually is secondary to GAS. Because streptococcal infection can be rapidly invasive and fatal, it was once common practice to administer penicillin prophylactically to all burned patients at the time of admission. The incidence of GAS infections in burned patients has decreased, probably secondary to immediate use of topical antimicrobial therapy. Routine administration of penicillin prophylaxis is not recommended because it can hasten colonization and potential infection with more resistant organisms. *S. aureus* also causes early septicemia. If there is concomitant inhalation injury, organisms that colonize the respiratory tract can cause bacteremia and invade the burn wound.

In the latter part of the first week after injury, environmental and endogenous gram-negative bacilli colonize the wound. *P. aeruginosa* and Enterobacteriaceae are usual. Colonization of the gut is probably the primary event, followed by bacterial translocation and wound colonization. Bacterial translocation is frequent in burned patients because of the disruption of the mucosal barrier from nutritional factors, immunosuppression, disturbance of the normal barrier of bowel flora (from selective pressure of antibiotic administration), and overgrowth of hospital-associated pathogens. Early institution of enteral nutrition satisfies caloric requirements, improves immune function and tissue healing, and preserves the mucosal barrier, thereby decreasing the incidence of septicemia in burn victims.[59] Another proposed mechanism for acquisition of environmental organisms and subsequent infection is immersion of the patient in water or rolling of the patient in soil in an attempt to control the burning at the time of injury.[60]

Complication of burn injuries by tetanus is uncommon in the United States. In the nonimmune patient who has a wound contaminated with *Clostridium tetani,* neurologic manifestations of tetanus toxin and minor local infection can occur in the first week after injury.[61] Tetanus immunization is administered routinely to burned patients who have not had boosters within 60 months. Tetanus immunoglobulin is given in addition to patients with heavily contaminated wounds whose immunization status is unknown or who have received fewer than three doses of adsorbed tetanus toxoid.[62]

Later Infections

During the second week after injury, gram-negative bacilli continue to be important pathogens, but the burn wound also becomes colonized with fungi. Risk factors associated with fungal wound infection are preceding antibiotic therapy, presence of indwelling central venous catheters, and infusion of parenteral nutrition, especially of solutions containing lipids. Colonization with *Candida* spp. is common in burned patients, but burn wound septicemia is infrequent. When invasive infection occurs, mortality exceeds 90% despite aggressive medical and surgical therapy.[63]

Fungi such as *Aspergillus* spp. and *Fusarium* spp. and members of the Mucoraceae family are rare causes of infection; infection with such organisms is invasive, however, and usually fatal. These infections frequently follow successful treatment of gram-negative bacillary infection with broad-spectrum antibiotics, and they occur in patients with acidosis. Fungi invade tissue rapidly and cause thrombosis, leading to tissue infarction and systemic dissemination. Extremely aggressive surgical measures are indicated urgently, but mortality remains high. Other fungi isolated from burn wounds are *Geotrichum, Rhodotorula, Cephalosporium, Penicillium, Trichosporon, Trichophyton,* and *Fonsecaea* spp.; these usually do not invade tissue.[64]

Special Sites of Infection

Anaerobic infections are rare in burned pediatric patients. Anaerobic bacteria have been found to colonize burn wounds around the mouth and anus and can have a synergistic role in burn wound infection, however.[65]

Infections of burns involving the ear cartilage can result in suppurative auricular chondritis, which causes pain, fever, and rapidly progressive edema of the auricle followed by liquefaction of cartilage. Avascularity of this tissue makes treatment difficult. Iontophoresis, a technique that uses direct current to drive charged compounds (antibiotics) into local tissues, has been used in conjunction with topical antimicrobial therapy and grafting, with encouraging results.[66,67]

Corneal infections secondary to direct thermal injury, chemical burn, or ectropion and desiccation can cause permanent scarring requiring corneal transplantation. In addition, infected corneal ulcers can perforate and cause herniation of the lens and loss of the eye. Globe exposure secondary to progressive contracture of burned eyelids and facial skin can require acute eyelid release.[68]

Pyomyositis can occur secondary to vascular compromise in deep burns that leads to muscle necrosis or from the unsuspected deep muscle injury in electrical burns. Intracompartmental infection in which there may be associated pyomyositis can result from delayed escharotomy or extravasation of infused fluids or can occur as a complication of splinting and positioning.[69] Treatment is surgical. Osteomyelitis and pyogenic arthritis can occur when bone and joints are exposed.

Other Infections

Respiratory Tract Infections

Pneumonia is the second most common bacterial cause of death in the burned patient.[70] In patients with inhalation injuries, pneumonia occurs most frequently in the first week after injury. Thermal damage produced by inhalation injury predisposes the airway to infection by (1) producing structural damage to the respiratory tract epithelium; (2) impairing surfactant production, mucociliary transport, and macrophage function; and (3) producing atelectasis. Pneumonia or tracheobronchitis occurs in up to 35% of those with inhalation injury.[20] Less commonly, pneumonia can result from hematogenous spread of infection from other areas, most notably the infected burn wound; this typically occurs late in the postburn period. A chest tube that must be placed through a wound can result in empyema and should be removed as soon as is practical.[20]

Sinusitis and otitis media are infectious complications of the child requiring nasotracheal intubation for inhalation injury.

Bacteremia

Bacteremia is not uncommon in the burned patient. Risk factors include wound manipulation and the presence of an intravascular catheter. Suppurative thrombophlebitis or infected intravascular thrombus can cause persistent bacteremia. Endocarditis must be considered in any patient with prolonged bacteremia. Bloodstream infections are the most common cause of bacteria-related death in patients with severe burns.[70]

Daily dressing changes and surgical wound debridement have been associated with bacteremia in 7.7% to 65% of episodes.[71–74] The greater the percentage of TBSA burned (and thus manipulated), the higher the risk for bacteremia. Use of prophylactic systemic antibiotics before burn wound manipulation, particularly debridement, has been shown to reduce the incidence of bacteremia but has not had a beneficial effect on subsequent clinical course or incidence of burn wound infection.[71,73,74] Bacteremia can occur in the absence of wound manipulation or other identifiable risk factors, presumably from translocation of gut organisms. Bacteremia secondary to burn wound manipulation or gut translocation usually is transient and does not result in infection at distant sites or interfere with graft adherence. It is possible, however, that the higher incidence of endocarditis demonstrated in burned patients is attributable to the increased number of episodes of transient bacteremia. Pyogenic arthritis and brain abscesses secondary to *S. aureus* bacteremia have been described.[75,76]

Catheter-Related Infections

Burned patients have a high risk for acquiring intravascular catheter-related infections. In one study, the rate of catheter-associated infection correlated inversely with the distance of the catheter insertion site from the burn wound; infection occurred more commonly when the insertion site was <30 cm from the burn wound.[77] Suppurative thrombophlebitis, both peripheral and central, also can occur in burned patients and is difficult to diagnose if the affected vein underlies the burn; prolonged antibiotic therapy, systemic anticoagulation, and need for surgery are considered.[20]

Urinary tract infections are common in burned patients, especially associated with urinary catheters commonly used to care for perineal burns or to monitor fluid status. Catheters placed for fluid status monitoring should be removed as soon as the patient's clinical status is stable, and their use should never be prolonged for the convenience of caregivers.

Intra-Abdominal Infections

Acute cholecystitis can occur in older children and adolescents with burns if enteral nutrition is not instituted. Findings include fever without localizing signs and serum hepatic enzyme abnormalities consistent with cholestasis (mimicking findings in septicemia). Acute pancreatitis and pancreatic abscess can occur in severely burned patients. Peritonitis, as a result of splanchnic ischemia, increased gastrointestinal permeability, and bacterial translocation, can occur.[20] Early enteral feeding decreases the likelihood of these complications.

Central Nervous System Infections

Infectious complications in the central nervous system are infrequent and usually are associated with bacteremia or endocarditis in patients with a burn >30% TBSA, possibly related to inability to localize infection. In a postmortem review of burned victims, 53% had central nervous system complications, 16% of which were infectious. Microabscess, septic infarction, and meningitis occurred, and most were caused by *S. aureus, Candida* spp., or *P. aeruginosa.*[78]

Viral Infections

Viral infections must be considered in any burn victim with unexplained fever whose burn wound is healing adequately.[79–82] Viral infections can occur at any time but are most common in the second week after injury and can be due to reactivation or acquisition. Herpes simplex virus (HSV) and cytomegalovirus (CMV) have been isolated from up to 30% of pediatric burned patients[79]; infection correlates directly with the TBSA involved.

CMV infection in burn patients is a purported cause of unexplained fever as well as hepatitis, neutropenia, and thrombocytopenia. Other serious manifestations of CMV infections, such as pneumonia, are infrequent. CMV infection can result from reactivation of latent infection or from primary infection. The cell-mediated immune dysfunction experienced by burned patients enhances reactivation of CMV and exacerbates symptomatic infection. Primary infection can be acquired from blood transfusions or cadaveric skin allografts from seropositive donors. CMV infection is associated with greater risk for bacterial infection in patients with burns.

Orolabial reactivation of HSV is common, and the virus can disseminate locally or cause infection of the burn wound, impeding wound healing; disseminated infection also has been described in burned patients.[83,84]

Other viral infections associated with excessive morbidity, delayed wound healing, or unexplained fevers are varicella-zoster virus, Epstein-Barr virus, and adenovirus. One study, performed before testing of the blood supply for hepatitis C virus (HCV), demonstrated that 18% of burned patients acquired HCV. Chronic hepatitis was observed in 83% of burned patients, which is a high rate in comparison with that in other populations.[85] Nosocomially acquired respiratory syncytial virus, adenovirus, and rotavirus add considerable morbidity during the protracted hospitalization.

Treatment

Specialized care in burn centers, the surgical trend toward aggressive early and repeated debridement and wound closure, and the routine use of topical antimicrobial agents contribute immensely to the prevention and control of infections after burns.

Topical antimicrobial therapy is a mainstay of burn care; such therapy has had an enormous effect on the rates of wound infection and septicemia. The general objectives of topical therapy are to decrease water vapor loss, prevent desiccation of exposed viable tissues, contribute to pain control, and inhibit bacterial and fungal growth.[20] Although topical agents do not sterilize the wound, numbers of colonizing organisms decrease, thus reducing the risk for bacterial invasion of underlying tissue. Topical agents commonly used in burned patients differ in their antimicrobial spectrum and side effects (Table 87.2). Other topical agents used in burn care are discussed in Chapter 294. There is no ideal topical antimicrobial agent. An agent is selected on the basis of defined and expected colonizing organisms, time after injury, knowledge of organisms indigenous to the burn unit, and possible adverse reactions. Initially, silver sulfadiazine usually is used, and subsequent choices are based on results of isolation of organisms from the wound. Topical antimicrobials have demonstrated decreased activity against both gram-positive and gram-negative multidrug-resistant organisms.[86] Silver sulfadiazine has fair to poor eschar penetration, unlike mafenide acetate, a carbonic anhydrase inhibitor, which is capable of eschar penetration.[20]

TABLE 87.2

Topical Antimicrobial Agents Commonly Used in the Treatment of Burns

Agent	Antimicrobial Activity Against				Adverse/Other Effects
	Gram-Positive Organisms	Gram-Negative Organisms	Anaerobes	Fungi	
Silver sulfadiazine (Silvadene, Thermazene)	++	+++	++	++	Allergic reaction in 5%, leukopenia in 5%–15%
Mafenide acetate (Sulfamylon)	+	+++	++	+	Allergic reaction in 10%, pain, metatbolic acidosis, pulmonary edema
Nanocrystalline silver dressings (Acticoat A.B., Silverlon)	++	+++	++	++	Limited toxicity, less painful than silver nitrate
Nitrofurazone (Furacin)	+++	+++	++	–	Dermatitis
					Fungal overgrowth

+++, excellent activity; ++, good activity; +, limited activity; –, no activity.

Data from Church D, Elyased S, Reid D, et al. Burn wound infections. Clin Microbiol Rev 2006;19:403–434; and Lipsky BA, Hoey C. Topical antimicrobial therapy for treating chronic wounds. Clin Infect Dis 2009;49:1541–1549.

Debridement of the wound is essential. Both enzymatic and chemical means of debridement have been used in the care of burns as alternatives to surgical excision. Proteolytic and mucolytic enzymes rapidly debride nonviable tissue but have been associated with a higher risk for septicemia.[87] The recently developed Versajet (Smith & Nephew) tool, which uses the Venturi effect to create a stream of water for cutting and a vacuum, has been shown to provide more precise excision compared with blade excision in adults and children and may decrease the time required for excision.[88,89] Temporary membranes also are available to use on superficial wounds or donor sites to decrease infection and facilitate comfort.[90] Fresh or reconstituted porcine xenograft, synthetic bilaminates, hydrofibers, semipermeable membranes, hydrocolloid dressings, and human allografts, including human amnion and chorion membranes, are examples, some of which are impregnated with silver to reduce bacterial and fungal growth.[91–93] Patients with heavily contaminated wounds or septicemia, or both, are best managed with allografts initially and later with autografts.[20] A Cochrane systemic review of randomized controlled trials comparing recombinant human growth hormone (rhGH), which increases protein synthesis, with any comparator, including placebo, demonstrated some evidence that rhGH used in both adult and pediatric large surface area burns could produce more rapid healing of the burn wound and donor sites without increased mortality or scarring but with an increased risk for hyperglycemia.[94]

Systemic antimicrobial therapy is only used when systemic infection is strongly suspected, but its role is adjunctive, and it never replaces aggressive surgical debridement and the use of topical agents. Parenteral agents should be of the narrowest antimicrobial spectrum possible, being directed specifically at known pathogens, to avoid colonization with resistant bacteria or fungi. In burned patients, the pharmacokinetics of antibiotics are altered as a result of the multiple pathophysiologic changes that occur after the burn injury.[95,96] These changes must be considered in selection of agents and optimal dosage.

Aminoglycosides have a short elimination half-life in adult and pediatric burned patients, thus requiring increases in both dose and frequency of administration.[97–100] Once-daily aminoglycoside dosing (8 mg/kg) in burned patients (TBSA burned, 18% to 81%) has been evaluated and was associated with elevation of creatinine >0.5 mg/dL in 35% of patients and ototoxicity in 1 of 13 patients.[101] Thus, without further study, once-daily aminoglycoside dosing cannot be recommended in burned patients. Vancomycin clearance is increased in burned patients, possibly because of increased renal tubular secretion; higher dosages may be necessary.[102] Because burned patients may have renal dysfunction, serum levels of aminoglycosides or vancomycin are monitored to allow individual adjustment of dosages.

The pharmacokinetics of ceftazidime, ticarcillin-clavulanate, imipenem-cilastatin, and aztreonam have been evaluated in burned patients.[96,103–106] Alterations were found for ticarcillin-clavulanate and ceftazidime (increased total clearance and volume of distribution) and aztreonam (increased volume of distribution). Creatinine clearance does not adequately predict dosage requirements for these drugs; thus, specific dosage recommendations were not made in any study. It seems prudent to use the highest recommended dose in a burned patient who does not have evidence of renal or hepatic impairment.

Management of Outpatients

Partial-thickness burns covering a small TBSA (<10%−15%) can be treated on an outpatient basis in the following circumstances: (1) the burns are not circumferential or do not involve the face, hands, feet, or perineum; (2) no other injuries are present; (3) child abuse is not suspected; and (4) the caregivers are capable of adhering to management and follow-up. Appropriate treatment of smaller burns is imperative because inadequate care can lead to wound infection, septicemia, poor wound healing, and a poor functional or cosmetic result.

Outpatient management of burns consists of cleaning the wound thoroughly and removing devitalized tissue. Small blisters can be left intact. Because large blisters can interfere with wound healing, most burn surgeons advocate debridement, whereas others believe that this increases the risk for infection. After cleaning and debridement, gauze dressing containing a broad-spectrum topical antibiotic such as silver sulfadiazine is applied. The dressing is changed with new application of antibiotic twice daily, and the parent or caregiver is educated about the expected changes in appearance of the wound. The wound is inspected 24 to 48 hours later to observe the expected healing, to detect signs of local infection, and to assess adequacy of parents' understanding of wound care.

Prevention

Prevention of infection in a burn is paramount to prevent mortality and morbidity. Urgent and adequate care of all burns and use of dressings impregnated with topical antimicrobial agents, followed by meticulous care and assessment, usually are successful. Early closure of the burn wound is the most protective treatment against infection. Pulmonary toilet in the patient with inhalation injury and rapid removal of intravenous and urinary catheters are essential in prevention of nosocomial infections. Strict attention to infection control practices is essential.

Routine use of prophylactic systemic antibiotics is not beneficial in prevention of infections and can predispose to colonization with resistant organisms.[107] Replacement therapy with immune globulin intravenous (IGIV) has been studied because most burned patients show a decrease in serum immunoglobulin G (IgG) concentration immediately after injury (mean values, 300 mg/dL), with a gradual return to normal after 14 to 60 days.[34,35] In one study, patients younger than 4 years had the most severe and prolonged decreases of IgG levels.[30] Patients with persistent serum IgG concentrations of <500 mg/dL may have a higher risk for septic complications.[31] Although IgG levels normalized with administration of IGIV in the patients studied (from mean of 400 mg/dL before infusion to >1200 mg/dL after infusion), no beneficial effect on development of septicemia was evident.[108] Administration of hyper-IgG against *P. aeruginosa* and *S. aureus* decades ago as adjunctive treatment for septicemia caused by these organisms in burned patients showed some beneficial effect.[109–111]

Interferon-γ, because of its ability to enhance macrophage activity and stimulate host immune responses, has been evaluated as prophylaxis for infectious complications in burned patients. In a European multicenter trial of 216 patients with severe burn injuries, administration of interferon-γ did not give protection from infectious complications or affect the mortality from infections.[112] A vaccine directed against *P. aeruginosa* was developed decades ago and shown to be efficacious.[113–117] In one study of 322 burned patients, administration of maximal-dose vaccine reduced the rate of invasive disease. A lower mortality rate was seen, however, only in patients who received parenteral antibiotic therapy and adjunctive hyperimmune globulin. Vaccination did not prevent colonization, and 90% of the patients had an adverse reaction to vaccination.[114] In 2000 a double-blind, randomized, placebo-controlled clinical trial of a *P. aeruginosa* vaccine involving 95 adult patients with burn injuries of ≥10% TBSA demonstrated high immunogenicity and a significantly lower incidence of *P. aeruginosa* bacteremia in vaccine recipients.[118] Additional controlled studies are required to assess the benefit of immunotherapy, in view of changes in predominant pathogens, improved supportive measures, and the trend toward early excision and wound closure.

Infection Following Bites

Marvin B. Harper, Sarah L. Wingerter

In the United States, it is estimated that 5 million bites occur every year, 90% of which are dog bites.[1] Dog bites alone result in approximately 330,000 emergency department visits (42% among children <14 years of age), 13,000 hospitalizations, and 20 deaths annually (mostly children).[2] Dogs, cats, and humans account for >90% of non–insect-related bite injuries, with rabbits and rodents responsible for most of the remainder.[1,3] Contact with wild animals and nontraditional pets poses a risk for both infection and injury. Worldwide, as many as 5 million people are bitten by snakes each year, with most bites occurring in Africa and Southeast Asia, and monkey bites represent up to 21% of animal bite injuries.[4] The trauma caused by these bites can be serious, and infection is the most common late complication.

Etiologic Agents

The organisms causing bite wound infections generally derive from the microbial flora of the biting animal's mouth rather than the victim's skin. Therefore the infecting organisms vary by species. Bite wound infections should be considered polymicrobial infections; in a large, prospective study of infected dog and cat bites, cultures done at a central reference laboratory yielded a median of five bacterial isolates per culture.[5] Mixed aerobic and anaerobic infection occurred in more than 50% of cases. Specimens sent concomitantly to local microbiology laboratories identified significantly fewer organisms, emphasizing the need for careful microbiologic analysis.

Table 88.1 shows the aerobic and anaerobic bacteria isolated from 50 patients with dog, 57 with cat, and 50 with human bite wounds.[5,6] *Pasteurella* spp. were the most common isolates from dog and cat bites, with *P. canis* the predominant organism isolated from dog bites and *P. multocida* the most common from cat bites. Other species isolated from these patients included streptococci, staphylococci, and *Moraxella* and *Neisseria* spp. Common anaerobic isolates included *Fusobacterium, Bacteroides, Porphyromonas, Prevotella, Propionibacterium,* and *Peptostreptococcus* spp. A number of other bacterial isolates previously had not been recognized as bite wound pathogens.

TABLE 88.1

Frequency of Isolation of Aerobic and Anaerobic Bacteria After 50 Dog, 57 Cat, and 50 Human Bite Wounds at Presentation for Management of Infection

	Dog	Cat	Human

++++, very common; +++, common; ++ not uncommon; +, occasional

Other studies confirm the polymicrobial nature of bite wounds.[7,8] *Pasteurella multocida* is only seen in animal bites, more commonly from cats,[9] whereas *Eikenella corrodens* and *Streptococcus pyogenes* are more closely associated with human bites, although they are sometimes seen with animal bites as well. *Capnocytophaga canimorsus,*[10,11] *C. cynodegmi,*[10] *Neisseria weaveri* (formerly M-5),[12,13] *Bergeyella zoohelcum,*[14] *Neisseria canis,*[15] *Staphylococcus intermedius,*[16] NO-1,[17] and *Paracoccus yeeii* (EO-2)[18] are all uncommon organisms to recover from general clinical specimens but are isolated from bite wound infections, particularly from dog bites.

The cause of infections resulting from bites of species other than humans, dogs, and cats is less well described. Simian bites appear to be similar to human bites in microbiology.[19] Polymicrobial infections with *Staphylococcus aureus, S. pyogenes, Pseudomonas aeruginosa,* and *Bacillus* spp. have been reported with camel bites.[20] Bites of large cat species such as leopards and tigers are associated with organisms typical of domestic cat bites, with isolation of *P. multocida* and *N. weaveri*.[21] Snake bites do not routinely require antibiotic management unless there is necrosis, in which case aerobic gram-positive cocci and gram-negative bacilli are thought to predominate.[22] A *Pasteurella caballi* infection was seen after a horse bite,[23] *Pasteurella aerogenes* and a *Chryseobacterium*-like organism have been isolated from infected pig bites,[24,25] *Actinobacillus* spp. have been reported from horse and sheep bite wounds,[26] and *Halomonas venusta* has been isolated from a fish bite.[27] In bites occurring in marine settings, organisms associated with water, such as *Vibrio* spp., *Aeromonas hydrophila, Plesiomonas shigelloides,* and *Pseudomonas* spp., have caused infections from bites of catfish, eel, crocodile, and swan.[28–32] Additionally, systemic diseases have been transmitted by bites, including tularemia from cats,[33] rat-bite (Haverhill) fever and sodoku from rats, herpesvirus B infection from monkeys, hepatitis B from humans, and leptospirosis from dogs and rodents. A rare infectious entity acquired from contact with seals, known as seal finger, is likely caused by a marine mycoplasma.[34] Human immunodeficiency virus (HIV) appears to be difficult to transmit by human bite.[35–37]

Epidemiology

Dog bites account for >90% of bite wounds that come to medical attention. The annual incidence of dog bites of children has been estimated at 1 to 3 per 1000 children per year[38–41] in developed countries, to rates as high as 26 per 1000 per year in developing countries.[42] Dog bite injuries alone account for 0.3% to 0.4% of all emergency department visits.[2,38] Data from the Agency for Healthcare Research and Quality indicate that in 2008 there were more than 300,000 emergency department visits and 9500 hospitalizations related to dog bites, an average of 866 emergency department visits and 26 hospitalizations per day.[43] The incidence and body part involved with dog bites vary by age. Children are more likely than adults to sustain a dog bite, with the highest risk in the second year of life and steadily decreasing each year thereafter (based on data from Austria) or with peak incidence in the 5- to 9-year age group (based on US data).[38,39] A recent study of patients receiving care for dog bites at a level 1 pediatric trauma center demonstrated a median age of 5 years, a male predominance, and a majority of dogs belonging to the patient's immediate or extended family.[44] Several studies have identified pit bulls as the most common breed involved in dog bites coming to medical attention.[44,45] Injuries to the face, head, and neck are most common, accounting for two thirds of dog bite injuries in preschool-aged children (extremities accounting for 27%). Injuries to the extremities (upper more than lower) become more common with increasing age, accounting for 55% beyond 14 years of age (at which age only 9% involve the head or neck).[39] Between 7% and 25% of children sustaining dog bites require hospital admission, depending on use of general anesthesia for primary wound management and the rate of infectious complications.[38,46]

Fatalities from bites occur primarily from massive blood loss after mauling by large dogs, particularly Rottweiler and pitbull-type dogs, or as the result of intracranial injury, particularly in smaller children.[47] Children <5 years of age are particularly vulnerable to attack and are more likely to sustain injury from smaller dogs. Overall, the relative risk for attack is significantly higher from

German shepherd, Doberman, pitbull, and Rottweiler breeds than from Labrador/retriever or cross-bred dogs, but because cross-bred dogs are so much more common, they represent the majority of bite injuries. Approximately 20 deaths occur each year in the United States as a result of dog bite attacks. Deaths due to infection after dog bites are uncommon but can occur as the result of septicemia or intracranial infection. In developing countries, rabies remains a significant late cause of death from dog bites. The estimated risk for infection in the otherwise healthy child depends on the location and extent of the dog bite injury and the initial management but is estimated to be 5% to 15%.

Cat bites are spread more evenly across age groups and cause less overall initial injury because cats have smaller mouths and less biting force, which results in less tearing of the tissues. However, their thin, sharp teeth produce small, deep wounds that are difficult to cleanse and are more likely to result in clinical infection, estimated to occur after 10% to 50% of bites.

Human bites may be sustained somewhat differently than bites of other animals and generally are defined as any disruption in the skin as a result of contact with the mouth. These can be self-inflicted (e.g., thumb-sucking resulting in skin breakdown, or self-injury as with autism), the result of a punch to the mouth of another person that results in a laceration of the hand, or the result of a typical bite but resulting from sexual activity or abuse that might be concealed from the medical provider. One study of human bite wounds in children seen at a single institution over a 6-year period identified 322 patients, representing 0.2% of all emergency department visits. Infection was seen in 9%, and 2%, overall, were hospitalized for treatment of infection.[48]

Table 88.2 displays the rate of infection of bite wounds from any source by bite site.[48,49] The two studies enrolled subjects at the time of initial evaluation in the outpatient setting. Bites to the hand are significantly more likely to become infected compared with bites at other sites. Wounds to the face are the least likely to become infected, probably because of its extensive vascularity. In one of these studies,[49] 12% of the wounds became infected, and the risk for infection differed on the basis of the biting species. Only 4% of 80 dog bites became infected, but 16% of 37 human bites and 50% of 22 cat bites became infected. Cat bites also can transmit *Bartonella* *henselae* and *Sporothrix schenckii*.[50,51] The paucity of reports regarding infection after rodent or rabbit bites makes the rate difficult to estimate, but it appears to be small, perhaps related to smaller and less penetrating wounds. Rat bites are associated with *Streptobacillus moniliformis* infections, hamster bites have caused *Francisella tularensis* and *Pasteurella aerogenes* infections,[52,53] and guinea pigs have caused *Haemophilus influenzae* infections.[54] Bat bite is important because it can transmit rabies virus. Infections transmitted by biting insects are addressed in other chapters.

TABLE 88.2

Rates of Infection of Bite Wounds by Body Site

Location of Bite	Rate (%)	No. Infected/No. Bites
Face/head/neck	6	3/49
Arm/leg	10	7/68
Trunk	10	1/10
Hand	28	21/76
Total	16	32/203

Data from Baker MD, Moore SE. Human bites in children. Pediatrics 1991;88:55; and Aghabian RV, Conte JE Jr. Mammalian bite wounds. Ann Emerg Med 1980;9:79.

Pathogenesis

Bite wounds become infected by inoculation of microorganisms into subcutaneous or deeper tissues. Modifying factors include the type and depth of inoculation, the amount of crush injury and devitalized tissue, the involvement of infection-prone structures, the ability to cleanse and debride the wound, and the pathogenicity of the infecting microorganism. Most series show a higher infection rate in bite wounds to the hand. Cat bites have the highest infection rates because of deep inoculation and high prevalence of *P. multocida* (Fig. 88.1). Dog bites are more likely to cause lacerations or avulsion injuries that are easier to clean and debride.

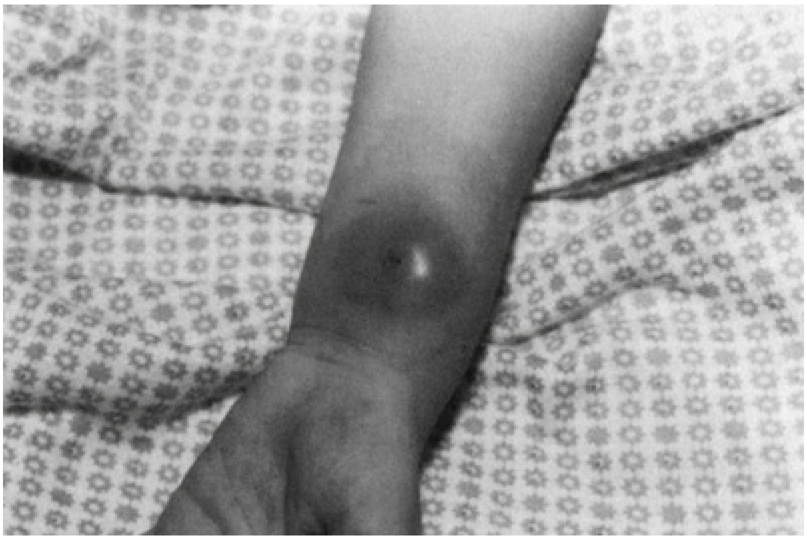

FIGURE 88.1 Cat bite abscess of the wrist with presentation for care delayed 1 month after injury. *Pasteurella multocida* was isolated in pure culture.

Most infections manifest as localized cellulitis or simple abscess. Infection can extend to adjacent areas, particularly if the teeth penetrate structures such as bones, joints, or the cranium. Regional lymphadenopathy, lymphangitis, fasciitis, toxic shock syndrome, septicemia, and shock also can develop. Septicemia occurs primarily in immunocompromised hosts, particularly asplenic individuals, who are prone to fulminant septicemia and shock with infection caused by *C. canimorsus*[55–59] or *Eubacterium plautii*[60] after dog bites.

Clinical Manifestations, Differential Diagnosis, and Clinical Approach

The history and physical examination readily lead to the likely organisms of most bite wound infections (Box 88.1). If infected, signs and symptoms (erythema, pain, tenderness, and swelling) almost always become apparent within 24 to 48 hours after the bite. Infections caused by *P. multocida* tend to have a more rapid onset, often within 12 to 18 hours. There may be purulent or serosanguineous discharge. Most patients are afebrile,[5] although fever can occur in patients with severe cellulitis or in the rare instance of bacteremia. Eschars at bite sites in individuals who appear ill may indicate *C. canimorsus* infection.[58]

Box 88.1

Key Elements of History and Physical Examination in Evaluating Bite Wounds With Regard to Possible Infection

History

The Animal

Record type of animal, health of animal, and whether attack was provoked or unprovoked, and consider the availability for testing or quarantine for signs of rabies, if applicable. Query whether local authorities notified (e.g., animal control or police officers)

The Patient

Consider special risks such as immunosuppression, asplenia, diabetes mellitus, antibiotic allergies, and history of tetanus and hepatitis B immunizations

Physical Examination

Systemic

Note state of well-being, fever, tachycardia, tachypnea, hypotension, or widened pulse pressure

Local

Note type of wound (e.g., puncture, laceration, avulsion), depth of penetration, involvement of underlying structures (e.g., joint, tendon, bone, cranial contents), extent of edema, erythema, tenderness (with measurements), range of motion, type of drainage (e.g., purulent, serosanguineous, malodorous), neurovascular function, lymphangitic streaking, and regional lymphadenopathy. Consider possibility of retained foreign body (e.g., tooth)

Even apparently trivial bites require careful evaluation for penetration of the skull or other body cavities or possible damage to underlying structures, such as joint spaces, bone, tendons, nerves, and blood vessels. The physician should consider the mouth size of the biter and, if there are puncture wounds, should examine carefully for punctures due to the apposing teeth. With cosmetically important bite wounds to the face in young children, there may be more life-threatening puncture wounds in the scalp or neck found only by careful examination.[61] Assessing deep structures is particularly important for scalp injuries that can penetrate the skull and for clenched-fist injuries in which joint or tendon injury could be missed.[62] Lacerations sustained when punching and striking teeth with a closed fist most commonly occur on the dorsal aspect of the third metacarpophalangeal joint and can be missed if the hand is examined only in the relaxed position. In addition, the initially linear path of injury becomes obstructed, hindering drainage of deep structures.

Paronychial infections in young children can result from thumb- or finger-sucking, and oral flora should be considered as a possible cause, especially when a history of injury is lacking. Herpetic whitlow, which can be confused with bacterial infection, should be suspected when erythematous or dusky-appearing vesicular or vesiculobullous lesions are present, particularly in cluster arrangement. Seal finger, which occurs in association with either seal bites or scratches or other contact with seals, has a longer incubation (4 to 8 days); edema and severe pain are prominent; and lymphangitis, lymphadenitis, and arthritis occur more frequently than in other bite wound infections.[63] Water organisms, such as *P. aeruginosa* and *Aeromonas* spp., should be considered after water animal bites.

Laboratory Findings and Diagnosis

Microbiologic confirmation of infection can be highly beneficial in management regardless of the biting species. Laboratory personnel should be notified to consider multiple isolates as pathogenic and to be vigilant for *P. multocida* or *E. corrodens.* Specimens should be sent for both aerobic and anaerobic bacterial culture (using anaerobic transport medium). For wounds contaminated by soil or vegetative debris, culture for mycobacteria and fungi should be considered. Gram stain and culture of fresh, uninfected bite wounds are not recommended because they do not predict the risk for subsequent infection or the pathogens that cause them.

Blood specimens for aerobic and anaerobic culture should be obtained from febrile children, particularly if they are immunocompromised or asplenic. Radiographs should be obtained after penetrating injuries overlying bones or joints, or when a fracture or a foreign body is suspected.

Management and Presumptive Therapy

Steps of Immediate Postexposure Management

1. **Evaluate the extent of injury and contamination.** New, uninfected bites should be carefully examined for foreign bodies, and visible dirt and debris should be sponged or irrigated away.

2. **Debride and cleanse the wound.** The wound should be copiously irrigated with sterile normal saline by high-pressure syringe irrigation, taking care not to inject into the tissue or inflict additional trauma.

a. *Consider use of a surgical-type scrub sponge for highly contaminated wounds*, especially if particulate matter is present. (Hibiclens or Betadine should not be used, unless diluted to 1% to avoid tissue toxicity. Agents such as Pluronic-68 or Shur-Clens are suggested.)

b. *Irrigate with ≥250 mL of saline*. There is no demonstrated benefit to irrigation with other solutions such as 1% Betadine solution or Pluronic F-68.[64] A recent Cochrane review indicated tap water may be a suitable alternative to saline for wound irrigation.[65] Antibiotic irrigation has not been shown to have additional benefit; rarely it may be used in special, high-risk circumstances. Animal models suggest high-pressure irrigation reduces bacterial wound counts better and reduces wound infection rates. Irrigation pressures of 5 to 8 pounds per square inch (psi) are recommended and correspond to gentle use of commercially available splash-guard shields (e.g., Zerowet) or an 18G catheter/needle attached to a 30- or 60-mL syringe.

c. Perform imaging to establish the presence or absence of foreign material such as embedded teeth or fragments as well as to identify bone damage.

d. Debride devitalized tissue and remove foreign material. Operative exploration and debridement should be considered if there is extensive tissue damage, involvement of a joint space, or cranial injury. There is no role for culture of the wound unless there is clinical evidence of infection.

3. **Consider wound closure.** The role of suturing, in general, is controversial. One study evaluated the practice of primary closure for mammalian bites in a series of 145 consecutive bites (88 dog, 45 cat, 12 human) treated with primary closure. Patients presented a mean of 2 hours after injury; 6% (95% confidence interval 2% to 9%) experienced wound infections, suggesting that when cosmesis is a primary concern, this rate of infection may be acceptable.[66] Increasing time to closure has been associated with increasing risk for infection, but more likely the time to closure is simply a proxy for the time to adequate wound cleansing. This has led to specific recommendations against closure for high-risk wounds >8 to 12 hours after the time of injury. No prospective or pediatric study has been performed to validate this approach with bite wounds. Until there are further data, it may be prudent to avoid primary closure if time since trauma is >8 hours or it is difficult to irrigate a deep puncture wound (unless the wound must be repaired for important cosmetic or functional reasons).[1,67] When closure is appropriate, the placement of a drain, microdrains, or only loose approximation of the skin is the optimal approach when feasible. The use of subcutaneous sutures has been associated with increased risk for

infection in retrospective studies, and their use should be avoided. An underused practice is delayed closure (after 48–72 hours) of this type of wound. Delayed closure has been recommended for human bites to the head and neck, especially those with exposed cartilage.[68] Elevation and immobilization of the wound are common practice.

4. **Consider postexposure prophylaxis.**

a. *Antibiotic prophylaxis*. The role of antimicrobial prophylaxis is discussed in Chapter 7. Limited data are available from clinical trials. A Cochrane analysis concluded that there is evidence that antibiotic administration significantly reduces infection rates with bites to the hand or human bites.[69] One meta-analysis suggested that antibiotic treatment also lowered the risk for infection after dog bites.[70] One small study randomized patients with human bite wounds to placebo or cephalexin-penicillin combination and identified a low rate of infection in both groups (1 of 62 individuals receiving placebo and 0 of 63 receiving antibiotic).[71] Antibiotic prophylaxis commonly is recommended for infection-prone bite wounds: moderate to severe wounds (especially if edema or crush injury is present), wounds that are difficult to clean or debride adequately, penetrating cat bites, and human bite wounds. Less severe wounds or more easily cleansed and dog bite wounds to areas other than the face, hands, feet, or genital area do not require antibiotic prophylaxis routinely. The ability of the host to control infection, should it occur, also is considered (Box 88.2).[1,62] The drug of choice is amoxicillin-clavulanic acid, which is given for 2 to 3 days. For penicillin-allergic patients, a combination of trimethoprim-sulfamethoxazole and clindamycin is recommended. All patients with bite wounds should be re-evaluated within 24 to 48 hours for signs of infection (Box 88.3).

Box 88.2

Indications for Infection Prophylaxis

Antibiotic Recommended

Characteristics of the Wound

Bite wounds of the face, hands, feet, or genital area

Wounds that cannot be reliably cleansed or completely debrided (e.g., deep punctures)

Bite wounds involving tendon, bone, or joint

Wounds with moderate or severe edema, crush injury, or devitalized tissue

Characteristics of the Host

Immunocompromised or asplenic host

Other Postexposure Prophylaxis Recommended

Hepatitis B

Begin vaccine if a human bite and the patient is not previously immunized. The use of hepatitis B immune globulin is limited to cases in which the biter is known to test positive for hepatitis B surface antigen

Human Immunodeficiency Virus (HIV)

Prophylaxis is limited to high-risk human bite exposures from a known HIV-positive biter (the need for HIV postexposure prophylaxis of bite wounds is uncommon)

Rabies

Administer rabies immune globulin and begin vaccine series for appropriate mammalian bites (see Chapter 228)

Tetanus

For patients who have received <3 doses of adsorbed tetanus toxoid or if immunization history is unknown, give:

1. DTaP if <7 years old, Tdap if ≥7 years old and has not previously received Tdap, or Td if previously has received Tdap

2. Tetanus immune globulin (TIG) or immune globulin intravenous (IGIV) if TIG not available
   For patients who have received ≥3 doses of adsorbed tetanus toxoid, give:

a. No tetanus booster if <5 years since last tetanus-containing vaccine dose

b. Tetanus booster if ≥5 years since last tetanus-containing vaccine dose (DTaP if ≤7 years old, Tdap if ≥7 years old and has not previously received Tdap, or Td if previously has received Tdap)

c. 3. No TIG

Box 88.3

Recommended Antibiotic Therapy

Wound Prophylaxis if Indicated

Amoxicillin-clavulanate; if penicillin-allergic, trimethoprim-sulfamethoxazole plus clindamycin

Treatment of Wound Infection

Oral therapy as above unless febrile, rapidly spreading, or high risk (then use parenteral therapy)

Parenteral therapy if indicated:

- Ampicillin-sulbactam (consider adding aminoglycoside if reptile or water-related species)
- If penicillin-allergic without anaphylaxis, consider using extended-spectrum cephalosporin or carbapenem (e.g., ceftriaxone, cefipime, or meropenem), *or* if severe allergy, use trimethoprim-sulfamethoxazole plus clindamycin and consider adding aminoglycoside if reptile or water-associated
- Vancomycin is considered in severe infections if methicillin-resistant *Staphylococcus aureus* (MRSA) is a possibility
- Clindamycin, doxycycline, or trimethoprim-sulfamethoxazole is considered for less serious, possible MRSA infection
- Bite wound infection can include many other pathogens in the immunocompromised host; treatment is individualized

b. *Tetanus prophylaxis.* Bites generally are not tetanus-prone injuries unless there is additional contamination with soil. They are, however, an opportunity to assess the patient's vaccination status. For persons with tetanus-prone injuries who have not completed their primary series, tetanus immune globulin and vaccine should be administered (see Chapter 188).

c. *Rabies prophylaxis*. The possibility of rabies must be considered after animal bites (see Chapter 228). Bites from bats are considered high risk for rabies in the US, and postexposure prophylaxis for these bites is routine. Local public health authorities can assist in determining the need for postexposure rabies prophylaxis for other bites.

d. *Consideration of systemic infectious agents related to human bites*. Hepatitis B, hepatitis C, and HIV could be transmitted potentially by a human bite. Hepatitis B prophylaxis should be considered for human bites. Human bites do not efficiently transmit HIV; postexposure prophylaxis for HIV is not routinely indicated but is considered in some special circumstances.[35,36]

e. *Consideration of cercopithecine herpesvirus 1 (herpes simiae or B virus) after bites from an Old World macaque monkey*. Little is known regarding the risk for infection after a monkey bite, but most macaque monkeys are seropositive for herpes simiae by 2 years of age, and more than 20 cases of transmission to humans have been reported with development of encephalitis (75% fatal). As a result, copious wound irrigation is recommended; irrigation with diluted sodium hypochlorite (household bleach diluted 1 : 10 with 0.9% saline) is considered, as is postexposure antiviral chemoprophylaxis with acyclovir or valacyclovir for 14 days.[72–74]

Most jurisdictions require bite injuries to be reported to the local health department. In cases with multiple or severe bites, there is a high risk for posttraumatic stress disorder, and referral for counseling should be considered.[75]

Empiric Management When Infection Occurs

When a patient comes to medical attention with an infected bite wound, basic principles of management should be followed. Sutured wounds should be opened, purulent collections drained, and necrotic tissue, foreign bodies, and debris removed. Specimens should be obtained for aerobic and anaerobic culture. Infected wounds should not be sutured. If bone or joint penetration has occurred, exploration and debridement of these areas may be necessary.

Empiric antimicrobial therapy should be based on pathogens that are most likely to be associated with the biting species and the clinical setting. Oral antibiotic therapy is appropriate for mild to moderate infections when adherence to the treatment plan is assured. Amoxicillin-clavulanic acid is an excellent choice because it provides activity against all common bite wound pathogens, including anaerobic bacteria, methicillin-susceptible *S. aureus, S. pyogenes, E. corrodens,* and *P. multocida.* Comparable parenteral agents, such as ampicillin-sulbactam or piperacillin-tazobactam, can be used for patients who require hospitalization because of rapidly spreading cellulitis or lymphangitis, large abscesses, bone or joint infection, or suspected sepsis. Appropriate alternative regimens include an extended-spectrum cephalosporin (cefotaxime or ceftriaxone) plus clindamycin. Trimethoprim-sulfamethoxazole has activity against *Pasteurella* and *Eikenella* spp., and a combination of trimethoprim-sulfamethoxazole and clindamycin is acceptable for individuals with a history of anaphylactic reactions to penicillins or cephalosporins. Antibiotics commonly used for other skin and soft tissue infections, such as the antistaphylococcal penicillins, first-generation cephalosporins, vancomycin, clindamycin, and erythromycin, are less active or inactive against *Pasteurella* and *Eikenella* spp. and cannot be used alone.[5,76] Azithromycin and fluoroquinolone agents have in vitro activity against the organisms that commonly cause bite wound infections,[77,78] but data on their clinical effectiveness are limited. Tetracycline is the treatment of choice for seal finger and also is active against most aerobic bacteria that cause bite wound infections, including *Pasteurella*.[77]

A 7- to 14-day course of antibiotic treatment usually is sufficient for infections limited to the soft tissues. A >3-week course generally is given for bone or joint infections. In all cases, the duration and route of antibiotic therapy should be individualized, based on the site, infecting organisms, antimicrobial susceptibility, and response to treatment.

Complications

The most common complications are related to tissue destruction. Soft tissue necrosis can result from infection or from crush injury during the bite. Pyogenic arthritis or osteomyelitis, particularly in cases in which diagnosis is delayed, can result in permanent injury to the joint or bone. Depending on the site of the bite, other complications, such as brain abscess, can develop.[79] Septicemia and meningitis can occur, especially in immunocompromised individuals.

Prognosis and Sequelae

Long-term follow-up studies of children sustaining bite wound infections are not available. In general, soft tissue infections that are treated promptly and appropriately are expected to heal completely, unless the injury itself has resulted in extensive tissue devitalization. Infections involving underlying bone, tendon, or joint structures have a more guarded prognosis for return to normal function. Goldstein[62] reported residual sequelae in 25% to 50% of patients after clenched-fist injury. In other series, permanent disabilities of the involved extremity were less common and often were related to delayed or inappropriate therapy.[80,81] A delay in therapy, particularly that caused by a failure to recognize deep (bone, joint, or tendon) involvement, may be the most important factor leading to poor outcome.

Prevention

Prevention of bites is most important. Education of the public to limit exposure of preschool-aged children to dogs, selection of specific dog breeds, spaying or neutering dogs (which makes them less likely to bite), and education of children on proper behavior around animals and the proper respect for dogs are important strategies. Healthcare providers should counsel parents regarding selection of appropriate pets, dog ownership, and avoiding dog breeds implicated most frequently in dog bite injuries and on matching pet size and temperament to a child's age and behavior.[1] Households with children younger than 8 years should avoid ownership of nontraditional pets such as ferrets, iguanas, or wild animals.[1] Proper cleansing and debridement of wounds remain the cornerstone for the prevention of wound infections, although antimicrobial prophylaxis also can play an important role in preventing infection for certain bite wounds.

Infections Related to Pets and Exotic Animals

Joseph A. Bocchini Jr.

Contact with animals can provide benefits for children and adults. However, exposure to nontraditional pets in the home and animals in public settings poses potential risks to children, including injuries and transmission of pathogenic organisms. Potential risks can be minimized or prevented by knowledge and use of educational materials, regulations, and guidelines that have been developed for this purpose.[1,2] Healthcare personnel (HCP), including pediatricians and veterinarians, can provide advice on selection of appropriate pets as well as prevention of disease transmission from nontraditional pets and when children contact animals in public settings.

Pet Exposures

Most households in the United States include one or more pets. In national surveys conducted by the American Pet Products Manufacturers Association, US households with one or more pets increased from 56% in 1998 to 65% (79.7 million homes) in 2015–16.[3] Numbers of households in the US owning pets were as follows: for dogs, 54.4 million; cats, 42.9 million; freshwater fish, 12.3 million; birds, 6.1 million; small animals (including sloths, porcupines, kinkajous, wallabies, sugar gliders, hedgehogs), 5.4 million; reptiles, 4.9 million; horses, 2.5 million; and saltwater fish, 1.3 million. Total US expenditures in the pet industry in 2015 were estimated at $60 billion.[3] In recent years, the number of families choosing nontraditional pets has increased.

Categories of Pets

Animals that become pets can be classified as *traditional* pets and *nontraditional* pets. Traditional pets generally include dogs and cats. Nontraditional pets include exotic animals, defined either as imported, nonnative species or species that originally were nonnative but now are bred in the US; indigenous wildlife; and wildlife hybrids (wildlife crossbred with domestic animals, producing offspring known as hybrids). The definition of nontraditional pets includes reptiles and certain species of mammals. In addition to exposure to animals in their homes, children may come in contact with animals in a variety of public settings.[2] Although there are many benefits to experiences with animals outside the home, contact with animals in public settings can be associated with substantial risks to children, including infections and injuries. These potential risks are exaggerated when there is inadequate understanding of disease transmission, methods of transmission prevention, or animal behavior, or lack of appropriate facilities for the care of animals.

Traditional Pets

Pets have become part of many families and are often considered to be extended family—living, eating, and even sleeping with human family members.[4] Among dog owners in the US, 53% consider their dog to be a member of the family, and 56% of dog owners sleep with their dogs next to them. In developed countries, 21% to 23% of dogs and 60% of cats sleep on or in their owner's bed.[4] Transmission of zoonotic agents by close contact between healthy traditional pets and family members through kissing, licking, or biting by pets or through vectors has been documented.[1,4–7]

In children, bite injuries are caused by a wide variety of traditional and nontraditional pets, but most wounds result in minor injuries and are not reported. Most systematic studies are limited to dog or cat bites. Bacteria from animal bites are reflective of the oral flora of the biting animal or less commonly of victim's own skin. The oral flora of the biting animal also may contain flora of ingested prey and other foods.[5]

Nontraditional Pets

Nontraditional pets are increasing in popularity among families because lifestyle choices of owners may favor smaller or more unusual pets. A survey by the American Veterinary Medical Association estimated that in 2011, 11% of US households owned “specialty or exotic pets” other than dogs, cats, birds, and horses, and the total population of exotic companion animals was estimated to be 8 million.[8] Table 89.1 provides examples of animals that are considered nontraditional pets as well as animals to which children may be exposed in public settings.

TABLE 89.1

Animals That Are Considered Nontraditional Pets and Animals That Can Be Encountered in Public Settings

Categories	Examples
Amphibians	Frogs, toads, newts, salamanders
Fish	Many types
Mammals	
Wildlife	Raccoons, skunks, foxes, coyotes, civet cats, tigers, lions, bears, kinkajous, coatis, olingos, ringtails, nonhuman primates
Domesticated livestock	Cattle, pigs, goats, sheep
Equines	Horses, mules, donkeys, zebras
Weasels	Ferrets, minks, sables, skunks
Lagomorphs	Rabbits, hares, pikas
Rodents	Mice, rats, hamsters, gerbils, guinea pigs, chinchillas, gophers, lemmings, squirrels, chipmunks, prairie dogs, hedgehogs
Feral animals	Cats, dogs, horses, swine
Birds	Canaries, finches, sparrows, parrots, parakeets, love birds
Reptiles	Turtles, lizards, iguanas, snakes, alligators
Arachnids	Spiders, scorpions, tarantulas
Insects	Madagascar hissing cockroaches, millipedes, stick insects

Modified from Pickering LK, Marano N, Bocchini JA, et al. Exposure to nontraditional pets at home and to animals in public settings: risk to children. Pediatrics 2008:122;876–886.

In addition to legal importation, there is a worldwide illegal trade in exotic animals, estimated at up to $10 billion annually,[9–10] only exceeded by the trafficking of arms and drugs. This illegal trade subverts rules established by regulatory agencies to reduce introduction of disease and potentially dangerous animals through importation restriction, inspection, and quarantine.[9]

Human contact with nontraditional pets and, specifically, with exotic animals raises several public health concerns. Most imported nonnative species are caught in the wild rather than bred in captivity. Health screening generally is not performed before shipment of these animals to the US, and often there is mixing of animal species in holding locations where exposure occurs of healthy animals to animals that might be ill, incubating, or asymptomatically carrying potential pathogens. In addition, the significant wildlife black market, through which a large number of exotic animals enter the US, compounds the risks for introduction of zoonoses.[10] After making the initial decision to acquire a nontraditional pet, owners may discover they are unable to provide the animal with the environment or nutrition required for a healthy life and often subsequently abandon or release the animal into the wild, posing risks for introduction of zoonotic disease, disruption of ecosystems, and injury to people, domestic wildlife, and the environment.

Diseases (Zoonoses) Associated With Nontraditional Pets

Zoonotic diseases or zoonoses are infections transmitted between other vertebrate animals and humans. Most emerging infectious diseases in humans are zoonotic in origin.[10–13] Of 1415 human pathogens, 61% are known to be zoonotic, and pathogens with multiple host species are twice as likely to be associated with an emerging infectious disease.[13] From 1980 to 2003, more than 35 new infectious diseases emerged in humans, many of which are zoonoses.[13] The leading causes of their emergence are human behavior and modifications of natural habitats, including expansion of human populations and encroachment on wildlife habitats, changes in food production processes, changes in agricultural practices, and global trade in wildlife.[9,10,14] Wild animals also can serve as reservoirs for transmission of zoonotic agents to domesticated animals and to humans.[12] Domestic animals and humans also can acquire zoonotic pathogens from exposure to nontraditional pets. An outbreak of tularemia in wild prairie dogs caught in the US and held in a commercial facility in Texas led to human transmission.[15] Some of the infected animals were distributed to a pet shop in Texas and were exported as far away as the Czech Republic.

Contact between animals from different areas of the world, including exotic animals imported into the US, can lead to disease in a new species and establishment of a pathogen in a new geographic area. In 2003, human monkeypox was introduced into the US. The source of monkeypox was imported African Gambian rats that were held in close proximity to prairie dogs being sold as pets. The prairie dogs became infected, which ultimately led to infection of humans with whom they had close contact.[16] Prompt recognition and public health efforts controlled this outbreak and may have prevented the establishment of monkeypox in North America.

Zoonotic transmission of bacteria, viruses, fungi, and parasites from household pets or animals to children through contact in their homes or public settings is common.[7] Transmission can be direct or indirect—through contact, aerosols, bites or scratches, contamination of the environment or food or water sources, or disease-carrying vectors. Animals can become ill but more commonly are asymptomatic carriers of specific organisms and can contaminate the environment to which children are exposed. Infants and children aged <5 years are at greatest risk, in part because they have suboptimal hygiene practices, have attraction to or curiosity about animals, and have developing immune systems, but also because these infections tend to be more severe in infants and young children.[17] People of all ages with primary or secondary immunodeficiencies are at risk for more severe zoonotic disease, as are pregnant women and elderly people.[18]

Reptiles and Amphibians

Reptiles pose a significant risk because of high carriage rates and intermittent shedding of *Salmonella* in their feces and because of persistence of *Salmonella* organisms in the environment.[17,19–21] A federal prohibition against commercial distribution of turtles with shells <4 inches in diameter was enacted in 1975 after investigations demonstrated that small turtles were a major source of human salmonellosis, particularly in children. This resulted in an important and sustained reduction of human salmonellosis. Despite this ban, however, illegal distribution of small turtles with subsequent human disease continues to occur.[22–25] In addition, young children without direct turtle exposure are at risk for turtle-associated salmonellosis through person-to-person transmission in childcare settings.[23] Amphibians also serve as a source of salmonellosis in households.[17,26] In the US, 6% of all sporadic *Salmonella* infections (11% among people <21 years of age)—approximately 74,000 cases annually—are the result of direct or indirect contact with reptiles or amphibians.[17]

Rodents

Contact with hamsters,[27] guinea pigs[28] and other rodents[29] purchased from retail pet stores has resulted in multistate outbreaks of salmonellosis. Hamsters have been associated with outbreaks of disease attributable to lymphocytic choriomeningitis virus (LCMV).[30] Guidelines for minimizing risk for human LCMV infection associated with pet rodents have been published.[31] Hedgehogs, originally from Europe, Asia, and Africa, have proved to be an important source of *Salmonella* serotype Tilene in the US.[32] *Yersinia pseudotuberculosis, Mycobacterium marinum,* rabies virus, and other *Salmonella* serotypes also are zoonotic pathogens carried by hedgehogs.

Plague, caused by *Yersinia pestis,* is enzootic among rodents in the western US. Humans become infected through bites of infected rodent fleas, inhalation of respiratory secretion from infected animals or humans, and handling of infected animals, especially rodents, lagomorphs, and domestic cats and dogs.[4,33–35] In parts of the US where plague is endemic, people with rodent-seeking animals can be exposed to *Y. pestis* through direct contact with plague-infected pets or their fleas.[4,34,35] People who live in areas where plague is endemic should follow a flea-control program designed by their veterinarians to keep their cats and dogs free from fleas.

Association with nontraditional pets also can result in skin infections, including ringworm, monkeypox, orf, cutaneous anthrax, tularemia, erysipeloid, ectoparasites, and endoparasites.[36–42] Hedgehogs pose a significant risk because their spines readily penetrate skin and can be the source of *M. marinum* and *Y. pseudotuberculosis* infections.[32]

Nonhuman Primates

Herpes B virus (cercopithecine herpesvirus 1) is a naturally occurring infectious agent that is endemic among macaque monkeys (including rhesus macaques, pig-tailed macaques, cynomolgus monkeys, and other macaques). Infected monkeys usually are asymptomatic or have mild oral lesions. Exposure occurs when monkeys are kept as pets or displayed in public settings. Herpes B virus infections in humans have been reported after animal bites, scratches, or percutaneous inoculation with infected material or splashes on mucous membranes. Human infections most often result in fatal meningoencephalitis.[43]

Fish

The major zoonoses transmitted by aquarium fish are mycobacterial infections,[44] but other organisms have been reported after exposure to aquarium water, tanks, filtration equipment, or other tank contents. Infection usually is sporadic and immunocompromised people have increased risk.[45–47] Typical organisms include *Aeromonas*, *Vibrio*, *Edwardsiella*, and *Salmonella* spp., *Streptococcus iniae*, and *Erysipelothrix rhusiopathiae.*[48]

Other Sources of Infection

Contact with chicks and other baby poultry purchased at agricultural feed stores have resulted in outbreaks of *Salmonella* infections.[49] The growing popularity of owning backyard poultry also has been linked to an increasing number of *Salmonella* outbreaks.[50] Parents who purchase these birds for their children or for fresh eggs generally are not often aware that *Salmonella* can be transmitted from live poultry to humans. In addition to direct exposure to animals, exposure to animal-derived pet food treats, such as pig ear chews, and to dry dog and cat food has resulted in human infections attributable to *Salmonella*.[51–53] Animals can become colonized after ingesting contaminated pet food treats, dry pet food, or raw meats. Animals can be asymptomatic and become unrecognized sources of contamination in the household. Handling contaminated pet food treats and pet food by humans also can result in infection.[52] In the US, pet treats are regulated by the US Food and Drug Administration (FDA). *Salmonella*-contaminated pet treats are considered adulterated under the Federal Food, Drug, and Cosmetic Act (21 USC §301−399). In 2004, the FDA initiated annual nationwide testing of pet treats for *Salmonella* spp. A multinational outbreak of antibiotic-resistant *Salmonella* was related to frozen feeder rodents.[54] Pet birds have been associated with the transmission of ectoparasites (mites), psittacosis, *Salmonella* spp., *Campylobacter* spp., and cryptococcus, among others.[55] From 2005 through 2009, 66 human cases of psittacosis were reported to the Centers for Disease Control and Prevention (CDC), most commonly after exposure to infected pet birds, usually cockatiels, parakeets, parrots, and macaws.[56]

Diseases Associated With Animals in Public Settings

Certain venues encourage or permit infants and children to come in contact with many different animal species (see Table 89.1) in a variety of public settings (Box 89.1), potentially resulting in millions of human-animal interactions annually. Infectious diseases, rabies exposure, injuries, and other health problems associated with these venues are well documented.[1,2,57] Of particular concern are instances in which zoonoses result in many people becoming ill. A systematic review of the literature documented that animal contact in pet stores and animals purchased from pet stores have been associated with the transmission of a wide spectrum of zoonotic infections.[58] Infections due to animals' enteric bacteria and parasites pose the highest risk in public settings. Although ruminant livestock (cattle, sheep, and goats) are the major source of infection, live poultry, reptiles, rodents, amphibians, and other domestic and wild animals also are potential sources.[2] These outbreaks have medical, public health, economic, and legal implications.

Box 89.1

Locations Where Contact With Animals in Public Settings Can Occur

Agricultural feed stores

Animal displays

Animal swap meets

Carnivals

Childcare facilities or schools

Circuses

County or state agricultural fairs

Educational farms or farm tours

Feed stores

Fish tanks

Livestock-birthing exhibits

Metropolitan zoos

Nature parks

Pet stores

Petting zoos

Rodeo events

Wildlife photography exhibits

Zoologic institutions

During 1996 through 2012, approximately 200 outbreaks of human infectious disease involving animals in public settings were reported to the CDC.[2] Most commonly, these involved enteric bacteria and parasites.[57] Serious infections with *Escherichia coli* O157:H7 and other Shiga toxin–producing *E. coli* (STEC) have been associated with multiple animals in public settings.[59–71] The primary reservoir of *E. coli* O157:H7 and other STEC is ruminant livestock, which are colonized asymptomatically. In many studies, the primary route of transmission has been foodborne,[65] including unpasteurized milk,[66] but person-to-person spread, direct animal contact, and contact with environmental items contaminated by animals are common.[61] Some pathogens are shed by animals intermittently and remain viable in the environment for months or longer.[72] In 2004 and 2005, there were 3 outbreaks in 3 states of *E. coli* O157:H7, accounting for 173 cases associated with direct and indirect animal contact at petting zoos.[62] Outbreaks[19] and sporadic cases of salmonellosis and outbreaks of cryptosporidiosis[73–75] have been described after visits to farms where visitors had either direct or indirect contact with animals. Additional illnesses after exposures in public settings include campylobacteriosis, tuberculosis, rabies, orf virus infection, giardiasis, tularemia, ringworm, and infected bites or wounds.[2,15,20,36,67,69,76,77] Poxvirus has been transmitted from pet rats to humans.[78]

The risk of human infection is increased by certain factors and behaviors, especially in children, including direct contact with animals (especially young animals), contamination of the environment or food or water sources, inadequate handwashing facilities or lack of education about hand hygiene, hand-to-mouth activities, lack of close supervision, and inappropriate layout and maintenance of facilities at animal exhibits.[2] For example, in a study of observations of practices at petting zoos in Canada, hand hygiene facilities were provided but often not used, items that would come into contact with mouths of infants and children (pacifiers, baby bottles, sippy cups) were carried into the petting zoos, and education about hygiene was lacking.[79] The recommendation to wash hands immediately after leaving an animal exhibit is the single most important prevention step for reducing the risk for disease transmission, even if an animal was not touched.

Rabies

People who have contact with rabid animals can be exposed to rabies virus through a bite or mucous membrane or wound contamination with infected saliva or nerve tissue.[80] Although human rabies deaths caused by animal contact in public exhibits have not been reported, exposures to rabid mammals at pet stores,[81] county fairs,[82] petting zoos,[83,84] and rodeo events[84] have required extensive public health investigations and medical follow-up. Raccoon-variant rabies in pet rabbits and a guinea pig has led to postexposure prophylaxis of adults and children.[85] Prevention of rabies in domestic cats, dogs, and ferrets can be achieved by regular rabies immunization and reimmunization.[80] Control of rabies among wildlife reservoirs is difficult, and use of licensed oral vaccines for mass immunization of free-ranging wildlife depends on the circumstances surrounding each animal rabies outbreak and is restricted to use through state and federal rabies-control programs.[80] No parenteral rabies vaccine is licensed for use in wild animals or hybrids. Because of the risk for rabies in wild animals (especially raccoons, skunks, coyotes, foxes, and bats), the American Veterinary Medical Association (AVMA), American Public Health Association, Council of State and Territorial Epidemiologists (CSTE), National Animal Care and Control Association, and National Association of State and Public Health Veterinarians (NASPHV) strongly recommend enactment and enforcement of state laws prohibiting importation, distribution, translocation, and private ownership of these animals. The AVMA has concerns about a number of aspects relative to ownership or possession of wild animals or hybrids, including the welfare of the animal, public health and safety, and environmental effects.[86]

Injuries and Allergies

Bites, scratches, kicks, falls, and crush injuries of hands or feet or from being pinned between an animal and a fixed object can occur at home or during exposure to animals in a public setting. Serious and fatal injuries can result from a large animal or any animal with aggressive behavior. Some nontraditional pets are chosen when they are young and small without consideration that they may grow into dangerous, aggressive adults. For example, iguanas sold shortly after birth measure <8 inches but by 2 to 3 years grow to several feet, and baby chicks become full-grown chickens and have a lifespan of up to 20 years.

An estimated 4 to 5 million animal bites occur in the US annually.[5] Although approximately 90% of bites are from dogs or cats, severe and fatal bites can occur from large or aggressive nontraditional pets. Animal bites or scratches often become infected. Infectious organisms, depending on the biting animal, include *Pasteurella multocida, Francisella tularensis, Capnocytophaga canimorsus*, *Staphylococcus* spp., *Streptobacillus moniliformis* (rat-bite fever), *Bartonella henselae* (cat-scratch disease), *Leptospira,* and herpes B virus. Tularemia occurred in a 3-year-old child bitten by an infected hamster purchased at a pet store.[42] Reptiles can produce injuries by bites, with claws, or with tails. Severe hand injury[41] and cellulitis[38] have been reported after green iguana bites. Between 33 and 50 nonnative (exotic) snake envenomations were reported annually in 2005–11 to US Poison Centers, 4% of which occurred in children <6 years of age, 3% in 6- to 12-year-olds, and 10% in 13- to 19-year-olds. Seventy percent of the envenomations occurred in a private residence.[87] Unprovoked attacks of children by ferrets, particularly of infants sleeping or lying down, can be severe, with mutilation of the ears or nose.[88,89] Attacks on sleeping infants are similar to those inflicted by rats.[90]

Although the frequency is not known precisely, the potential for having an allergy to nontraditional pets is likely to be substantial. The American Academy of Allergy, Asthma, and Immunology estimates that approximately 15% of the population experiences allergies to dogs and cats,[91] usually owing to sensitization to their dander, scales, fur, feathers, body waste, or saliva. Flea bites also can lead to allergic manifestations. Hives have been described in people who have contact with hedgehogs.[92] Although scaly animals are not as likely to be as allergenic as furry animals, there are case reports of allergic rhinitis, asthma, and contact hypersensitivity reactions to iguanas.[40] In addition, an iguana bite–induced hypersensitivity reaction has been reported.[41]

Reportable Diseases Acquired From

Nontraditional Pets and Animals in Public Settings

Many national and state notifiable diseases can be transmitted from animals. Public health officials at state health departments and the CDC collaborate in determining which infectious diseases should be nationally notifiable; states determine which diseases are reportable within states. A disease may be added to the national or state list as a new pathogen emerges or removed if disease incidence decreases. Because disease reporting varies by state, specific requirements should be obtained from relevant state health departments. Provisional data are published weekly in the *Morbidity and Mortality Weekly Report,* and final data are published each year by the CDC in the annual "Summary of Notifiable Diseases," which can be found online (http://www.cdc.gov/mmwr/mmwr_nd/index.html). These data are necessary for study of epidemiologic trends and development of disease prevention policies. HCP should report suspected cases of human illness to local and state health departments as soon as possible, including when the patient has a history of visiting an animal in a public setting during his or her incubation period.

Prevention Measures

HCP and veterinarians play an important role in guiding parents and their children about prevention of risks associated with ownership of traditional and nontraditional pets as well as contact with animals in public settings. Parents and pet owners typically lack knowledge about the multiple modes of transmission of zoonotic infectious diseases from pets. Although pediatricians recognize the importance of anticipatory guidance about pet-related hazards, only 5% reported that they regularly educated patients or families about pet-associated salmonellosis or toxoplasmosis.[93]

Pediatricians and veterinarians together can remind parents, children, and pet owners about the importance of measures to avoid illness. Simple and effective advice includes frequent handwashing and avoiding direct contact with animals and their environments. This is particularly important with animals from which transmission of enteric pathogens is a risk, including young ruminants, young poultry, reptiles, rodents, amphibians, and animals who are ill. Young children always should be supervised closely when in contact with animals in public settings. The NASPHV has developed an excellent compendium with standardized recommendations for use by public health officials, veterinarians, animal venue operators, animal exhibitors, visitors to animal venues and exhibits, and others concerned with disease control and with minimizing risks associated with animals in public settings.[2]

To reduce the possibility of injury, HCP should remind pet owners about matching the size and temperament of a pet to the age and behavior of an infant or child, providing direct supervision of younger children, and educating all children about appropriate human-animal interactions.

The decision to obtain a nontraditional pet by parents with children in the household is often not discussed with HCP or veterinarians. However, as trusted sources of healthcare information, HCP and veterinarians are in a unique position to offer information and advice to families who already have or are considering the purchase of a nontraditional pet. Informational brochures and posters available for display or referral to websites can educate parents without significantly increasing time of healthcare visits. Proper pet health maintenance, immunization, flea and tick control, deworming, and diet and activity can minimize the risk for infection or injury and ensure health of the pet. Referral to a veterinarian also can be helpful when parents are contemplating purchase of a nontraditional animal. Veterinarians can provide information about appropriate pet selection, the size of an animal when it attains adulthood, the temperament as well as husbandry needs of an animal, and suitability as a pet.

A history of contact with pets in the home or animals in public settings should be part of every well-child evaluation and especially should be part of an evaluation of a suspected infectious disease. A history of nontraditional pets in the home or contact with animals in public settings can lead to specific testing and additional or optimized management and occasionally will result in early identification of an unusual infection from another part of the world.

Recommendations and Guidelines

Recommendations for dealing with nontraditional pets and exposures to animals in public settings have been developed by several organizations including the American Academy of Pediatrics, whose recommendations are summarized in Box 89.2. The NASPHV and CDC have established recommendations to prevent disease outbreaks associated with animals in public settings.[2] The CDC has issued recommendations for preventing transmission of *Salmonella* from reptiles to humans[23] and information regarding health risks from *Salmonella* posed by contact with baby poultry.[49] Guidelines for prevention of zoonoses in immunosuppressed people also are available.[18,94]

Box 89.2

Guidelines for Prevention of Human Diseases Acquired From Nontraditional Pets at Home and Exposure to Animals in Public Settings

General

- Wash hands immediately after contact with animals, animal products, or their environment
- Supervise handwashing for children <5 years of age
- Wash hands after handling animal-derived pet treats
- Never bring wild animals home, and never adopt wild animals as pets
- Teach children never to handle unfamiliar, wild, or domestic animals even if the animals appear friendly
- Avoid rough play with animals to prevent scratches or bites
- Do not permit children to kiss pets or put their hands or other objects into their mouths after handling animals
- Do not permit nontraditional pets to roam or fly freely in the

house or allow nontraditional or domestic pets to have contact with wild animals

- Do not permit animals in areas where food or drink are prepared or consumed
- Administer rabies vaccine to mammals as appropriate
- Keep animals clean and free of intestinal parasites, fleas, ticks, mites, and lice
- People at increased risk for infection or serious complications of salmonellosis (e.g., children <5 years of age, elderly people, and immunocompromised hosts) should avoid contact with animal-derived pet treats

Animals Visiting Schools and Childcare Facilities

- Designate specific areas for animal contact
- Display animals in enclosed cages or under appropriate restraint
- Do not allow food in animal-contact areas
- Always supervise children, especially those <5 years of age, during interaction with animals
- Obtain a certificate of veterinary inspection for visiting animals and/or proof of rabies immunization according to local or state requirements
- Properly clean and disinfect all areas where animals have been present
- Consult with parents or guardians to determine special considerations needed for children who are immunocompromised or who have allergies or asthma
- Certain animals are not recommended in schools, childcare settings, and hospitals. These include nonhuman primates, inherently dangerous animals (lions, tigers, cougars, bears,

wolfdog hybrids), mammals at high risk for transmitting rabies (bats, raccoons, skunks, foxes, coyotes), aggressive animals or animals with unpredictable behavior, stray animals with unknown health history, reptiles, and amphibians

- Ensure that people who provide animals for educational purposes are knowledgeable regarding animal handling and zoonotic disease issues

Public Settings

- Venue operators must know about risks for disease and injury
- Venue operators and staff must maintain a safe environment
- Venue operators and staff must educate visitors about the risk for disease and injury and provide appropriate preventive measures

Animal-Specific Guidelines

- Children <5 years of age and immunocompromised people should avoid contact in public settings with reptiles, amphibians, rodents, ferrets, baby poultry (chicks, ducklings), and any items that have been in contact with these animals or their environments
- Reptiles, amphibians, rodents, ferrets, and baby poultry (chicks, ducklings) should be kept out of households that contain children <5 years of age, immunocompromised people, or people with sickle cell disease and should not be allowed in childcare facilities
- Reptiles, amphibians, rodents, and baby poultry should not be permitted to roam freely throughout a home or living area and should not be permitted in kitchens or other food-preparation areas
- Disposable gloves should be worn when cleaning fish aquariums, and aquarium water should not be disposed in sinks used for food preparation or for obtaining drinking water
- Mammals at high risk for transmitting rabies (bats, raccoons,

skunks, foxes, and coyotes) should not be touched by children

Modified from Pickering LK, Marano N, Bocchini JA, et al. Exposure to nontraditional pets at home and to animals in public settings: risk to children. Pediatrics 2008:122;876–886.

The AVMA supports the view that exotic animals, wildlife, and wildlife-domestic hybrids do not make good pets. These animals are dangerous and are a hazard to human health, other animals, and the environment. The AVMA also recommends that ferret owners have knowledge about the species and stress that no one who is incapable of removing himself or herself from the bite of a ferret should be left unattended with a ferret. Measures to control and prevent psittacosis in humans and birds were published by a committee formed by the NASPHV and were endorsed by AVMA, CSTE, and the Association of Avian Veterinarians.[56]

Guidelines for animals that might have contact with children in childcare settings have been published by the National Resource Center for Health and Safety in Child Care and Early Education.[95] These guidelines state that any pet or animal present at the facility (indoors or outdoors) should be in good health, show no evidence of carrying any disease, be fully immunized, and be maintained on a flea-, tick-, and worm-control program. A current (time-specified) certificate from a veterinarian should be on file in the facility, stating that the specific pet meets these conditions. All contact between animals and children should be supervised by a caregiver who is close enough to remove the child immediately if the animal shows signs of distress or the child shows signs of treating the animal inappropriately. The caregiver should instruct children on safe procedures to follow when in close proximity to animals—for example, not to provoke or startle animals or touch them when they are near their food. Potentially aggressive animals should not be in the same physical space with children. The facility should not keep or bring in turtles, iguanas, lizards, or other reptiles; ferrets; psittacine birds; or any wild or dangerous animals. Recommendations for handwashing by staff, volunteers, and children, as well as maintenance of animals housed on the premises, are provided in the guidelines.[95] In addition to exposures to animals within a center, childcare and school field trips can result in disease.

HCP and veterinarians are encouraged to work together to educate one other and to communicate a common message to pet owners regarding the benefits and risks of pet ownership and of contact with animals outside the home. Joint training seminars and joint sponsorship of health communication campaigns in pediatrician and veterinarian offices would greatly increase awareness of pet owners. The One Health initiative supported by AVMA to increase veterinary collaboration with counterparts in human medicine is an excellent step forward to benefit clinical medicine and public health and will build and reinforce partnerships between the professions to create a holistic approach to reduce human illness and injury related to animal contact.[96] A conceptual framework to support "one-health research" for policy on emerging zoonoses has been published.[97]

Tickborne Infections

Kristina Bryant

Ticks are obligate blood-sucking arthropods that transmit a variety of pathogenic organisms, including bacteria, viruses, and protozoa.[1–4] Along with mites, ticks are arachnids of the subclass Acari. More than 800 species comprise two major families within the suborder Ixodida.[1] Hard-bodied ticks (family Ixodidae) are distinguished from soft-bodied ticks (family Argasidae) by the presence of a dorsal sclerotized plate or scutum. A third family, the Nuttalliellidae, contains a single species of tick found only in southern Africa.

Hard ticks may survive for several months to 3 years, whereas soft ticks may live for more than 10 years and are highly resistant to starvation.[1] The longevity of ticks serves to perpetuate the pathogens that they carry.

Epidemiology

Although ticks are found throughout the world, individual species have evolved with requirements for specific hosts, habitats, and climates. Most tickborne diseases also have a specific geographic distribution (Table 90.1).[2–8] Several factors influence the incidence of tickborne infections. Human factors include the degree and duration of exposure to tick-infested habitats and host immunity. Tick-related factors include the prevalence of ticks and their usual hosts, infection rates, seasonal activity, and the relative likelihood of individual species to feed on humans.

TABLE 90.1

Tickborne Diseases: Agents, Vectors, and Geographic Distribution

Disease	Agent	Principal Vectors	Approximate Distribution
Lyme disease	*Borrelia burgdorferi*	*Ixodes scapularis, I. pacificus, I. ricinis*	Northeast, Midwest, and West of United.States; Europe
Babesiosis	*Babesia microti, B. duncani, B. divergens*	*Ixodes scapularis, I. ricinis*	Northeast, upper Midwest, and West (e.g., Washington, California) of US; Europe
Rocky Mountain spotted fever (RMSF)	*Rickettsia rickettsii*	*Dermacentor variabilis* (American dog tick), *D. andersoni* (Rocky Mountain wood tick), *Rhipicephalus sanguineus* (brown dog tick)	*D. variabilis:* widely distributed east of the Rocky Mountains and in limited areas of Pacific Coast. *D. andersoni:* Rocky Mountain states and Southwestern Canada *Rhipicephalus sanguineus:* widespread but associated with disease transmission in southwestern US and along the US-Mexico border)
***Rickettsia parkeri* rickettsiosis**	*Rickettsia parkeri*	*Amblyomma maculatum* (Gulf Coast tick)	East and South of US, especially coastal regions
***Rickettsia species* 364D–associated spotted fever**	*Rickettsia species* 364D	*Dermacentor occidentalis (Pacific Coast tick)*	US Pacific Coast (e.g., northern California)
Mediterranean spotted fever (MSF)	*Rickettsia conorii*	*Rhipicephalus sanguineus*	Mediterranean region, Africa, Western Asia
Human monocytic ehrlichiosis	*Ehrlichia chaffeensis*	*Amblyomma americanum* (lone star tick)	Southern and middle Atlantic regions of US, north and south central regions of US; isolated areas of New England
Human granulocytic anaplasmosis	*Anaplasma phagocytophilum*	*Ixodes scapularis, I. pacificus*	New England; north central and Pacific regions of US
***Ehrlichia ewingii* infection**	*Ehrlichia ewingii*	*Amblyomma americanum* (lone star tick)	Southeastern and south central regions of US; isolated areas of New England
Southeastern tick–associated rash illness (STARI)	Not identified	*Amblyomma americanum* (lone star tick)	South central region of US
Tularemia	*Francisella tularensis*	*Amblyomma americanum, Dermacentor variabilis, D. andersoni*	All US states except Hawaii; Europe, Asia
Powassan virus disease	Powassan virus	*Ixodes cookei, I. marxi, I. spinipalpus, Dermacentor andersoni*	Maine, New York, Michigan, Minnesota, Wisconsin, Virginia
Colorado tick fever virus disease	Colorado tick virus	*Dermacentor andersoni*	Western US and southwestern Canada (elevations of 4000 to 10,000 feet)
Tickborne	Tickborne	*Ixodes ricinus, I. persulcatus*	Europe and northern parts of

encephalitis virus disease	encephalitis virus		Asia
Tickborne relapsing fever	*Borrelia hermsii*, *B. miyamotoi*	*Ornithodoros* species, *Ixodes scapularis*, *I. pacificus*, *I. ricinus*, *I. persulcatus*, *I. ovatus*, *I pavlovski*	Worldwide, US, Canada, Europe, Russia, Asia
Crimean-Congo hemorrhagic fever	Crimean-Congo hemorrhagic fever virus	*Hyalomma marginatum* complex	Europe, Asia, Africa

Not all diseases caused by ticks are infectious. Tick paralysis may result after exposure of the host to neurotoxic substances produced salivary glands of engorged female ticks, usually after attachment for at least 5 days.[9,10] This rare disease manifests as ataxia or acute flaccid paralysis without sensory loss or pain. Symptoms may be confused with botulism or Guillain-Barré syndrome. Most cases occur in children, with girls affected more often than boys.[11] There are no diagnostic tests for tick paralysis. The diagnosis is made by finding an embedded tick and watching for improvement after tick removal. Symptoms usually resolve within 24 hours.[9,10]

Cases of tick paralysis have been reported worldwide, and 43 tick species have been implicated.[12] In North America, most episodes occur in the western United States and Canada and are associated with *Dermacentor andersoni* or *D. variabilis*. Cases cluster in April through June, when *Dermacentor* species ticks emerge from hibernation.[9]

Pathogenesis

The tick life cycle includes three stages: larvae, nymph, and adult. Both the larva and the nymph must take a blood meal to progress from one stage to the next. Hard-bodied ticks feed slowly over several days and only once per stage. Soft-bodied ticks may take up to 10 short blood meals (i.e., minutes to hours) that involve multiple hosts. Ticks become infected with microorganisms when this blood meal is taken from an infected host. Some pathogens (e.g., *Borrelia* spp., *Rickettsia* spp., *Francisella tularensis*) are also transmitted transovarially and transtadially (i.e., from larva to nymph to adult), allowing ticks to serve as reservoirs and vectors. Horizontal transmission when ticks are cofeeding on a host has been described but is rare.

Transmission of pathogens to humans usually occurs when the feeding site of an attached tick is contaminated with infected salivary secretions, regurgitated midgut contents, feces, or coxal fluid.[2] The duration of tick attachment necessary for transmission varies widely. Transmission of bacterial agents usually requires more than 24 hours, although *Anaplasma phagocytophilum* can be transmitted more rapidly.[13] Tick-borne encephalitis virus (TBEV) is transmitted within minutes of a tick bite, and early removal does not decrease transmission.[14] Transmission occasionally occurs in the absence of attachment, as is seen when nonintact skin or conjunctiva are touched after crushing an infected tick.

Clinical Manifestations

A careful travel history can help determine which pathogens should be considered in a patient with signs and symptoms consistent with a tickborne illness. A history of recent tick bite and occupational or recreational exposures that could result in tick exposure should be sought, but their absence does not exclude infection with a tickborne illness. Because tick bites are usually painless, individuals with confirmed tickborne illnesses may be unaware of their exposure to ticks. For example, in several published case series, tick bites were reported by only about 60% of those with confirmed Rocky Mountain spotted fever (RMSF) and 68% of people with ehrlichiosis.[15–17] Tick bites may confused with spider bites, chigger bites, or other insect bites. Because clustering of some tickborne illnesses is well-documented, similar illness in family members, other close contacts who share environmental exposures, or even pet dogs should prompt consideration of tickborne infection.[18]

Fever, headache, malaise, arthralgia, and myalgia are features common to many tickborne diseases and a variety of other infectious and noninfectious conditions. It is therefore not surprising that many tickborne diseases represent a diagnostic challenge. As many as 75% of patients ultimately proved to have tickborne rickettsial disease are given another diagnosis when they first seek for medical care.[19,20] Tickborne rickettsioses, for example, must be differentiated from a variety of other illnesses that cause fever and a maculopapular or petechial rash, including human herpesvirus 6, enterovirus, group A *Streptococcus*, human parvovirus B19, and *Neisseria meningitidis* infection.[21] As with bacterial sepsis, hypotension and disseminated intravascular coagulation also can occur.[22] Gastrointestinal tract manifestations, including anorexia, nausea, vomiting, and diarrhea, are often reported with tickborne diseases.[23] Severe abdominal pain mimicking acute appendicitis has been described with RMSF.[24]

The erythema migrans skin lesions seen with Lyme disease and southeastern tick-associated rash illness (STARI) can be confused with bacterial cellulitis, eczema, tinea corporis, granuloma annulare, and insect envenomations.[25] Lyme arthritis must be distinguished from septic arthritis, postinfectious arthritis, and rheumatologic disease. A variety of pathogens, including *F. tularensis*, *Bartonella henselae,* and several *Rickettsia* species, have been associated with a syndrome characterized by a scalp eschar at the site of tick attachment and neck lymphadenopathy.[26] When the eschar is overlooked, any of these diseases can mimic cat-scratch disease or bacterial lymphadenitis due to *Staphylococcus aureus* or group A *Streptococcus*.

Concomitant pharyngitis or malaise can suggest Epstein-Barr virus infection. The symptoms of babesiosis overlap with those of malaria. The differential diagnosis for tickborne relapsing fever includes diseases characterized by recurrent or biphasic fever patterns, including malaria, yellow fever, dengue fever, brucellosis, leptospirosis, rat-bite fever, chronic meningococcemia, and some African hemorrhagic fevers. Heartland virus, a phlebovirus, shares clinical manifestations with *Ehrlichia* and *Anaplasma*, including fever, leukopenia, and thrombocytopenia.[8]

Clinical clues and common laboratory abnormalities that suggest tickborne diseases are provided in Table 90.2, along with characteristic skin findings.[8,27,28] The spectrum of illness for more recently described infections has not been fully elucidated.

TABLE 90.2

Clinical and Laboratory Manifestations of Selected Tickborne Illnesses

Disease	Clinical Clues	Skin Findings	Common Hematologic Abnormalities	Other Laboratory Abnormalities

Lyme disease[29–32]	Monoarticular arthritis Aseptic meningitis Facial nerve palsy	Erythema migrans (single or multiple)	Leukopenia Thrombocytopenia	Hepatic transaminase elevation
Babesiosis[33]	Malaria-like illness with fever, hepatosplenomegaly, and jaundice	Rash not usually detected	Anemia (severe) WBC count normal to mildly decreased Elevated reticulocyte count Thrombocytopenia Decreased haptoglobin Positive direct Coombs test	Hepatic transaminase elevation (mild) Hemoglobinuria Elevated lactate dehydrogenase Elevated BUN, creatinine
Rocky Mountain spotted fever[20,34]	Febrile illness with rash, headache, myalgias	Maculopapular rash in >90% of children, often involving the palms and soles; may become petechial	Thrombocytopenia CSF pleocytosis (<100 cells) with moderate protein elevation	Hyponatremia Hepatic transaminase elevation
***Rickettsia parkeri* rickettsiosis**[6]	Febrile illness with myalgia, headache, lymphadenopathy	Eschar at inoculation site Multiple eschars in <20% Maculopapular or less commonly petechial rash; may involve palms or soles	Thrombocytopenia, leukopenia	Mild hepatic transaminase elevation
Mediterranean spotted fever[35–37]	Febrile illness with rash, headache, myalgia, and lymphadenopathy	Eschar at site of tick bite Maculopapular rash on trunk, extremities, palms and soles (96% of children)	Lymphopenia Thrombocytopenia	Hepatic transaminase elevation Elevated lactate dehydrogenase
Human monocytic ehrlichiosis[38–41]	Febrile illness with rash, headache, myalgias	Petechial, maculopapular, or diffuse erythema (66% of children)	Leukopenia Thrombocytopenia CSF pleocytosis (<100 cells) with moderate protein elevation	Hepatic transaminase elevation
Human granulocytic anaplasmosis[42]	Febrile illness with headache, myalgias	Rash rare	Leukopenia Thrombocytopenia	Hepatic transaminase elevation
***Ehrlichia ewingii* infection**[43]	Febrile illness with headache, myalgias	Rash rare	Leukopenia Thrombocytopenia	Hepatic transaminase elevation

Southern tick–associated rash. illness[44–46]	Mild Lyme-like illness manifesting outside a Lyme-endemic area	Erythema migrans–like	Usually normal	Not reported
Tularemia[47–50]	Regional lymphadenopathy Pulse-temperature dissociation	Papule or necrotic ulcer at site of tick bite	—	—
Powassan virus[51]	Meningitis or meningoencephalitis Profound muscle weakness Hemiplegia	—	—	Lymphocytic pleocytosis in CSF
Colorado tick fever virus[52]	Biphasic febrile illness with fever, myalgias	Maculopapular or petechial rash in 5%-12%	Leukopenia Atypical lymphocytosis Thrombocytopenia	Lymphocytic pleocytosis in CSF with elevated protein level
Tickborne encephalitis (TBE) virus[53–55]	Biphasic illness with meningoencephalitis occurring 7 days after self-limited, flu-like illness		Initial leukopenia; thrombocytopenia later Leukocytosis	Elevated hepatic transaminases Moderate PMN pleocytosis in CSF
Tickborne relapsing fever[56,57]	Recurring febrile episodes lasting 2–7 days Headache, myalgia, chills, nausea, vomiting, arthralgia Jarisch-Herxheimer reaction with antibiotic therapy	Petechiae concentrated in the trunk, extremities, and mucous membranes	Thrombocytopenia	Hematuria Proteinuria
Crimean-Congo hemorrhagic fever[58,59]	Febrile illness with rash, myalgia and mucosal bleeding Tonsillopharyngitis common	Maculopapular rash Petechiae	Leukopenia Lymphopenia Thrombocytopenia	Elevated AST Hematuria Proteinuria
Heartland virus[8]	Fever, fatigue, anorexia headache, nausea, diarrhea myalgia, arthralgia	Not described	Leukopenia Thrombocytopenia	Elevated hepatic transaminases

[a] Mortality rates are higher for immunocompromised patients and asplenics.

[b] Requires biosafety level 4 facilities.

[c] Among the initial six patients described with this disease, one patient with multiple comorbidities died.

AST, aspartate aminotransferase; BUN, blood urea nitrogen; CSF, cerebrospinal fluid; PCR, polymerase chain reaction; PMN, polymorphonuclear cell; WBC, white blood cell.

Tickborne infections can be asymptomatic, and symptomatic infections range from mild, self-limited illness to severe disease and death.[60–62] Case-fatality rates of selected pathogens in the absence of treatment are provided in Table 90.2. Some tick species are vectors for multiple pathogens, and a single tick bite may result in two or more simultaneous infections.[63,64] Concurrent bacterial and viral infections have been described.[65] Coinfections may result in atypical clinical manifestations or increased severity of disease.[66,67]

Diagnosis

Because different tick species are known to transmit specific pathogens, the ability to identify ticks may assist with diagnosis. Pictorial guides are available.[68] Estimating the degree of engorgement can suggest the duration of attachment and therefore the potential risk of infection. Testing ticks for pathogens is not routinely recommended for clinical diagnosis. Diagnostic strategies are outlined in Table 90.2.

The clinician should be aware of the limitations of current diagnostic tests, especially serology. Antibody tests may be negative at the onset of symptoms, necessitating acute and convalescent serology. Asymptomatic or clinically inapparent infection can result in high seroprevalence rates for some tickborne disease in endemic regions.[69,70] Antibodies can persist for years after infection and may exhibit significant cross-reactivity. For example, *A. phagocytophila* and *E. chaffeensis* have a more than 50% cross-reactivity.[71] Serologic cross-reactivity also has been seen between *B. burgdorferi* and several other organisms, including other relapsing fever *Borrelia*, *Ehrlichia*, and *Leptospira* species.[72] This cross-reactivity makes knowledge of clinical and ecologic factors associated with these diseases essential for diagnosis.

Treatment

Detailed treatment recommendations can be found in pathogen-specific chapters. Severe or fatal disease may result when treatment is delayed, and prompt, empiric antibiotic therapy with doxycycline is essential when spotted fever rickettsioses, ehrlichiosis, or anaplasmosis are suspected. A retrospective cohort study failed to reveal dental staining, enamel hypoplasia, or tooth color differences involving children younger than 8 years of age who were treated with doxycycline for suspected RMSF.[73] Doxycycline also is the preferred treatment for tickborne relapsing fever and for children 8 years or older with early Lyme disease.

Macrolides, including azithromycin and clarithromycin, are alternatives for the treatment of some tickborne infections.[74,75] Trimethoprim-sulfamethoxazole therapy has been associated with increased severity of ehrlichiosis and should be avoided when this diagnosis is considered.[76] Intravenous gentamicin is recommended for the treatment of tularemia, although fluoroquinolones also are active against *F. tularensis.* Most cases of babesiosis may resolve without treatment, but quinine plus clindamycin or atovaquone plus azithromycin are indicated for severe disease.

Supportive care is indicated for the most viral tick-transmitted diseases. Ribavirin has been used to treat Crimean-Congo hemorrhagic fever, but the quality of evidence supporting a benefit is low and is derived primarily from observational studies.[77]

Prevention

Avoidance of tick-infected areas remains a key strategy for the prevention of tickborne illnesses. When tick habitats cannot be avoided, wearing a hat, long-sleeved shirt, pants, socks, and closed-toe shoes may prevent ticks from reaching the skin. Light-colored clothing permits visualization of crawling ticks. Outer clothing may be treated with permethrin. This synthetic pyrethroid should be sprayed onto each side of the fabric in well-ventilated areas only, and treated items should be allowed to dry completely before they are worn.[78] This insecticide retains its potency for 2 or more weeks, even if clothing is laundered.

N,*N*-diethyl-*m*-toluamide (DEET) is an over-the-counter tick repellant used on skin. Although rare toxicity has been reported with inappropriate or excessive use, the product is safe when used as directed on children.[79,80] For children 2 months of age or older, products with up to 30% DEET are recommended.[81] DEET-containing products are not recommended for children younger than 2 months of age. Products containing picaridin, oil of eucalyptus, IR3535, and 2-undecanone have also been registered by the US Environmental Protection Agency for use as tick repellants, but hourly protection times vary considerably.[82]

Those living in tick-endemic areas should be educated about tickborne diseases and the need to perform routine checks for ticks after possible exposures.[83] After leaving grassy and wooded areas, skin should be inspected for ticks. Prompt removal of ticks may prevent the transmission of pathogens. Common sites of tick attachment include the scalp, waist, armpits, groin, and under socks and the beltline. Ideally, attached ticks are grasped with tweezers or fine-tipped forceps and are removed with gentle, steady pulling perpendicular to the skin. Use of folk remedies, including application of gasoline, kerosene, fingernail polish, petroleum jelly, or a lit match, are never recommended for tick removal.[84]

Controlling tick populations is difficult and may have adverse environmental consequences.[85] In selected areas, populations of black-legged nymphal ticks and lone star ticks have been reduced through the use of deer feeding stations that result in the transfer of a topical acaricide to the animal.[86] In residential areas, landscape management practices can reduce potential exposure to ticks. These include removal of leaf litter, tall grasses, and brush around homes and using wood chips or gravel between lawns and wooded areas.[87] Judicious use of a chemical control agent also is beneficial, and a single springtime application of an acaricide has been shown to reduce the population of ticks that cause Lyme disease by 68% to 100%.

Control of host reservoirs is another potentially important prevention strategy for some tickborne diseases. For example, rodent-proofing homes is recommended in areas where tickborne relapsing fever is endemic.[88] Keeping pet animals free of ticks also is recommended.

Most tickborne diseases are not vaccine preventable. Distribution of a vaccine developed for the prevention of Lyme disease was discontinued in 2002, with the manufacturer citing insufficient consumer demand.[89] Two inactivated vaccines for the prevention of tickborne encephalitis virus are licensed in Europe.[90] The pediatric formulation of FSME-IMMUN (Baxter, Austria) is available for children 1 to 15 years of age, and the pediatric formulation of Encepur (Novartis, Germany) is recommended for children 1 to 11 years of age. The adult formulation of FSME-IMMUN also is licensed in Canada. Both vaccines are well-tolerated and immunogenic, with seroconversion rates approaching 100%.[91–93]

The primary series of FSME-IMMUN and Encepur consist of three doses, with an initial booster dose after 3 years. Subsequent booster doses are given every 3 to 5 years, depending on age, local epidemiology, and national recommendation. Travelers to endemic areas may be vaccinated according to an accelerated schedule that varies by vaccine.

Individuals who develop fever within 4 weeks of a known tick bite should undergo medical evaluation. However, prophylactic antibiotics after a tick bite to prevent bacterial diseases are not routinely recommended. Even in areas where tickborne diseases are endemic, limited numbers of ticks are infected with pathogenic organisms.[94] The efficacy of preventive antibiotics varies. For example, antibiotic therapy delays but does not prevent the symptoms associated with RMSF.[95]

According to guidelines published by the Infectious Disease Society of America, prophylaxis to prevent Lyme disease may be considered when all of the following criteria can be met. First, the attached tick is reliably identified as an adult or nymphal *Ixodes scapularis* tick that is estimated to have been attached for 36 or more hours based on the degree of engorgement or certainty about time of exposure. Second, antibiotics can be started within 72 hours of the time the tick was removed. Third, ecologic information indicates that the local rate of infection of *I. scapularis* ticks is at least 20%. Fourth, doxycycline is not contraindicated.[96] A single dose of doxycycline (200 mg for adults or 4 mg/kg up to 200 mg/dose for children ≥8 years) is the only recommended prophylactic regimen.

Standard precautions are indicated for the care of hospitalized patients with most tickborne infections. A notable exception is Crimean-Congo hemorrhagic fever virus, for which blood and body fluids of infected patients are highly infectious and healthcare-associated outbreaks have been reported.[97] Strict observation of droplet and contact precautions, along with thorough environmental disinfection are necessary.

91

Clinical Approach to the Infected Neonate

Jessica E. Ericson, Daniel K. Benjamin Jr.

Neonates are uniquely susceptible to infection. An immature immune system is coupled with exposure to the variety of maternal and environmental pathogens that can affect this population.

This chapter outlines the clinical approach to the neonate with signs or symptoms consistent with infection. Supportive measures should be the first priority: respiratory support, correction of metabolic and hematologic derangements, fluid management, and use of inotropic drugs when indicated. The clinician then should obtain diagnostic studies and institute antimicrobial therapy considering the timing of infection and the neonate's previous exposure to maternal and environmental factors.

Etiologic Agents

Timing is important in determining the cause of neonatal infections. Infections can be acquired prenatally, perinatally, or postnatally (Table 91.1). Detailed discussions of infections can be found in Chapters 92, 93, and 94.

TABLE 91.1

Periods of Transmission of Neonatal Pathogens[36]

Pathogen	**Prenatal**	**Perinatal**	**Postnatal**

x, period of transmission.

Epidemiology

Infections acquired in utero result from organisms such as *Toxoplasma gondii*, rubella virus, cytomegalovirus (CMV), herpes simplex virus (HSV), parvovirus B19, hepatitis C virus, Zika virus, and *Treponema pallidum*. These infections typically result from transplacental transmission. Risk of transmission depends on the trimester of pregnancy during which the maternal infection occurs. For example, *Toxoplasma* transmission rates range from almost 0% during the first weeks of pregnancy to 60% in the third trimester.[1]

Severity of the infection also depends on the stage of pregnancy at which maternal infection occurred. Congenital toxoplasmosis, parvovirus B19, and rubella acquired during the first trimester often result in stillbirth or severe anomalies. Transmission of infection often depends on whether the maternal infection is a primary infection or a recurrence. For example, almost 40% of neonates born to mothers with a primary CMV infection during pregnancy are infected, and most infections are associated with signs and symptoms at birth, whereas less than 2% of neonates are infected in pregnancies of CMV-infected, seropositive mothers.[2]

Perinatal infections are acquired just before birth (often after rupture of membranes) or as the neonate passes through the birth canal. The neonate initially is colonized after exposure to maternal microflora, including with nonpathogenic organisms such as *Lactobacillus, Peptostreptococcus,* and *Saccharomyces*. However, the neonate also can be exposed to potential pathogens such as group B *Streptococcus* (GBS) and other bacteria, HSV, human immunodeficiency virus (HIV), hepatitis B virus, CMV, and *Candida* species. Perinatally acquired infections can manifest any time from immediately after birth to weeks or months later (e.g., HIV). Early-onset sepsis (<72 hours of life) typically is caused by perinatally acquired infections. Risk factors for early-onset sepsis include preterm delivery, prolonged rupture of membranes (>18 hours), maternal fever, and chorioamnionitis.[3,4] Although GBS is still the most common cause of early-onset sepsis, the institution of intrapartum chemoprophylaxis has decreased the incidence of GBS early-onset sepsis by 70%.[5] Chorioamnionitis is a major risk factor for early-onset sepsis predominantly in prematurely born neonates, and *Escherichia coli* is the most common cause.[6,7]

Late-onset sepsis (4 to 30 days of life) can be caused by perinatally or postnatally acquired organisms. The incidence of late-onset sepsis and meningitis caused by GBS has not been reduced with the use of intrapartum chemoprophylaxis.[5] Late-onset and late-late onset (>30 days of life) infections are found increasingly in very low birth weight (VLBW) neonates.[8] Common organisms include *Staphylococcus aureus, Enterococcus* species, or gram-negative bacilli that are likely to be acquired from the environment rather than periantally.[8,9] Coagulase-negative staphylococci, once the most common cause of catheter-associated bloodstream infection (BSI), and *Candida* spp. that cause late-onset BSI have receded dramatically in neonatal intensive care units using bundled best practices of infection prevention.[10]

Clinical Manifestations

Although a variety of organisms can cause congenital infections, some aspects of the clinical presentation frequently occur independent of the underlying cause (Table 91.2). Intrauterine growth retardation (IUGR), jaundice, hepatosplenomegaly, rash, intracranial calcifications, microcephaly, chorioretinitis, and thrombocytopenia can be manifestations of several congenital infections. Although many sequelae of congenital infections are present at birth, others (e.g., hearing loss, developmental delay) can manifest months or years later.

TABLE 91.2

Characteristic Manifestations of Congenital Infections

Manifestation	Toxoplasma	Rubella	CMV	Treponema	Parvovirus B19	VZV	Herpes	Ent
Anemia	x	—	—	x	x	—	—	—

CMV, cytomegalovirus; IUGR, intrauterine growth retardation; VZV, varicella-zoster virus; x, manifestation of the disease.

From Neu N, Duchon J, Zachariah P. TORCH infections. Clin Perinatol 2015;42:77–103.

Early-onset bacterial septicemia often is nonfocal and fulminant in onset, in contrast to late-onset sepsis that can progress more slowly and often manifests as a focal infection (e.g., meningitis, urinary tract infection, pyogenic arthritis, osteomyelitis, pneumonia). More than 90% of neonates with early-onset sepsis have clinical manifestations in the first 24 hours, with most of the remainder within 48 hours of birth.[11]

Signs of perinatally and nosocomially acquired septicemia often are nonspecific and subtle, but bacteremia is uncommon in asymptomatic neonates.[11,12] Signs consistent with neonatal systemic infection can include temperature instability, lethargy, irritability, apnea, respiratory distress, hypotension, bradycardia, tachycardia, cyanosis, abdominal distention, hyperglycemia, hypoglycemia, jaundice, and feeding intolerance.[12,13] These signs overlap with those of other diseases in the neonatal period, including anemia, congenital heart disease, respiratory distress syndrome, and metabolic disorders.

Laboratory Findings and Diagnosis

If bacterial or fungal infection is suspected, prompt investigation should be accompanied by administration of empiric antimicrobial therapy. White blood cell counts and acute phase reactants such as C-reactive protein (CRP) have poor positive predictive values for septic neonates (14% for neonates at risk for sepsis).[14,15] There currently are no screening laboratory tests with sufficient sensitivity and specificity to discriminate among well-appearing neonates at risk for early-onset sepsis.[7]

For bacterial and fungal infections, culture of normally sterile body fluids remains the gold standard for diagnosis. The sensitivity of blood culture to detect candidemia and bacteremia depends on a collection of at least 0.5 mL blood,[16–18] and this volume may not detect low levels of bacteremia or candidemia.[14] Although obtaining multiple-site blood samples concurrently may help distinguish between cultures contaminated with skin flora and those representing true infection,[19] obtaining serial blood cultures increases detection by only a few percentage points. Sensitivity of blood cultures also can be compromised by antibiotic administration to the mother intrapartum or to the neonate.

The incidence of bacterial meningitis is higher in the first month of life than at any other time and complicates approximately 25% of BSIs.[20] Diagnosis of meningitis and identification of the offending organisms require examination of cerebrospinal fluid (CSF). Unless neurologic signs are present at the time of the sepsis evaluation, some clinicians defer performance of lumbar puncture unless the blood culture detects a pathogenic organism.[21] Blood cultures, however, can be negative for neonates with meningitis. Blood cultures were negative for 38% (35 of 92) of neonates 34 or more weeks' gestational age with meningitis in one study[22] and 34% (45 of 134) of VLBW neonates with culture-proven meningitis in another study.[23] The delay inherent in waiting for a positive blood culture to obtain CSF cultures decreases the likelihood of confirming meningitis.[24] The American Academy of Pediatrics and the Centers for Disease Control and Prevention recommend that a lumbar puncture be performed when neonatal sepsis is suspected provided that the infant is stable enough to tolerate the procedure.[3,25]

A urine culture should be obtained as part of the sepsis evaluation of neonates after the third day of life, but it has limited utility before this age.[26] Urine cultures should be obtained by suprapubic aspiration or in-and-out bladder catheterization. Bag specimens are difficult to evaluate due to frequent contamination and can lead to unnecessary antibiotic administration and imaging studies.

Disseminated HSV can manifest as sepsis with or without vesicular skin lesions; clues are hepatic dysfunction and consumptive coagulopathy. Evaluation of neonates suspected of having HSV infection should include viral cultures or DNA polymerase chain reaction testing performed on swabs obtained from the conjunctivae, mouth, skin, anus, CSF, and blood.[27]

Table 91.3 outlines the primary diagnostic tests for congenital infections. Characteristics of the clinical presentation and a review of the maternal history and laboratory test results can provide additional clues to the priority of pathogen testing.

TABLE 91.3

Diagnostic Tests for Congenital Infection[36]

Pathogen	Method
Cytomegalovirus	Shell vial, culture on urine; DNA PCR on plasma; IgM antibody in serum
Human immunodeficiency virus	DNA PCR on plasma
Parvovirus B19	DNA PCR on plasma; IgM antibody in serum
Rubella virus	IgM antibody in serum; culture from nasal specimen
Varicella-zoster virus	IgM antibody in serum; DNA PCR on plasma, lesions
Herpes simplex virus	DNA PCR on CSF and plasma; culture or DNA PCR of skin-eye-mouth lesions or swab specimens from mouth, nasopharynx, conjunctiva if no lesions
Treponema	Quantitative nontreponemal test on serum; CSF VDRL test; dark-field examination for spirochetes, direct fluorescent antibody test of lesions
Toxoplasma	Detection of IgM or IgA antibody in serum; DNA PCR on plasma, CSF, or urine

CSF, cerebrospinal fluid; IgM, immunoglobulin M; PCR, polymerase chain reaction test; VDRL, Venereal Diseases Research Laboratory.

Management: Empiric and Definitive Therapy

A high index of suspicion and timely, empiric antimicrobial therapy are important in the management of septicemia in neonates. Ampicillin plus an aminoglycoside are the most commonly used antibiotics.[28] Ampicillin provides coverage for gram-positive infections (e.g., GBS, *Listeria monocytogenes*). Gentamicin is active against most gram-negative pathogens causing early-onset disease (e.g., *E. coli,* other Enterobacteriaceae) and provides synergy with ampicillin against GBS and *Listeria*. Cefotaxime, a third-generation cephalosporin with superior CSF penetration compared with gentamicin, may be considered in cases of suspected or proven gram-negative bacillary meningitis. However, the use of empiric cefotaxime rather than gentamicin among infants at birth has been associated with an increased risk of death among term and preterm infants[29] and development of invasive candidiasis and necrotizing enterocolitis in premature infants.[30,31] Vancomycin or nafcillin sometimes is substituted for ampicillin for suspected nosocomial infections, especially in the setting of an indwelling central venous catheter.

After the organism and its susceptibilities are available, antibiotic therapy should be changed to the narrowest effective regimen. Vancomycin should not be continued unless a pathogen is identified that is resistant to β-lactam agents. Duration of antibiotic therapy typically is 10 days for a confirmed uncomplicated BSI. For meningitis caused by GBS, the usual duration of therapy is 14 to 21 days, and for enteric bacilli, the duration is at least 14 days after sterilization of CSF or 21 days total, whichever is longer. Increasingly, magnetic resonance imaging (MRI) is performed near anticipated end of therapy to detect cerebritis, infarction, or abscesses that may lengthen therapy.

Although uncommon in term infants, the cumulative incidence of candidemia among extremely low birth weight neonates (<1000 g) may be as high as 9%.[32] Empiric therapy for *Candida* should be considered for hospital-associated infection in symptomatic neonates with risk factors for fungal infections, including extreme prematurity, thrombocytopenia, and recent exposure to broad-spectrum antibiotics.[32] Options for antifungal therapy include amphotericin B deoxycholate, lipid products of amphotericin B, fluconazole, and micafungin.

Empiric high-dose acyclovir therapy should be considered for neonates with elevated hepatic transaminase levels, skin-eye-mouth lesions consistent with herpes infection, maternal peripartum HSV infection, and those who do not improve with antibiotics and have negative blood cultures at 48 hours.[33] The use of acyclovir empirically is debated.[34,35]

Bacterial Infections in the Neonate

Morven S. Edwards, Carol J. Baker

Perspective

Neonatal sepsis and pneumonia account globally for approximately 500,000 deaths annually and almost 50% of deaths of infants 7 through 27 days of age.[1] The mortality rate in developed countries also is substantial, estimated at 5% to 10%. Neonatal sepsis is characterized by systemic signs and bloodstream infections (BSIs) occurring in the first month of life. The survival of very low birth weight (VLBW) (<1500 g) and extremely low birth weight (ELBW) (<1000 g) infants in the United States and other resource-rich countries has expanded use of this terminology to infants requiring prolonged hospitalization for complications of prematurity.

Etiologic Agents

Over past decades, the incidence of early-onset sepsis has declined in developed countries, and that of later-onset sepsis has remained unchanged or has increased.[2] The incidence of early-onset group B streptococcal (GBS) infection has declined by 85% to about 0.25 cases per 1000 live births, in association with implementation of maternal intrapartum antibiotic prophylaxis.[3] The predominant pathogens causing early-onset bacterial infections continue to be

GBS and *Escherichia coli,* which together account for approximately 70% of infections (Table 92.1).[2,4,5] Most infants with early-onset sepsis due to GBS are term (≈75%), and most with *E. coli* are preterm (≈80%).[6] The remaining early-onset infections are caused by other streptococci, including viridans streptococci and *Enterococcus;* enteric gram-negative bacilli; and *Listeria monocytogenes* or other maternal genital flora. Maternal vaginal colonization with methicillin-susceptible *Staphylococcus aureus* (MSSA) or methicillin-resistant *S. aureus* (MRSA), although uncommon, poses potential for vertical transmission and resultant neonatal infection.[7]

[a] Includes late onset and late, late onset.

+++, commonly associated; ++, frequently associated; +, occasionally associated; −, rarely associated.

In late preterm infants (34 to 36 weeks' gestational age), gram-positive organisms cause most cases of early-onset sepsis,[8] but among VLBW infants, GBS has declined, and the relative importance of *E. coli* has increased.[9,10] More than one half of early-onset infections in a cohort of VLBW infants at centers of the National Institute for Child Health and Human Development Neonatal Research Network (NICHD NRN) were caused by gram-negative enteric organisms, especially *E. coli*.[11] Each of the bacteria causing early-onset sepsis can cause late-onset disease. Septicemia due to *E. coli* or GBS remains common (see Table 92.1).

The predominant organism among VLBW neonates is coagulase-negative staphylococci (CoNS), which can occur in association with a medical device (e.g., intravascular catheter), result from a gastrointestinal disorder (e.g., necrotizing enterocolitis), or occur de novo.[2,12] Among VLBW infants, most late-onset infections are caused by gram-positive organisms (70%), and CoNS accounted for almost one half of infections in the NICHD NRN.[13] True infection, based on isolation of CoNS from two or more blood cultures or one blood culture and a sterile site, is unlikely in infants with a birth weight exceeding 2000 g or gestation exceeding 34 weeks.[14] Infection rates due to CoNS can be reduced with implementation of infection-prevention initiatives.[15]

Gram-negative enteric bacilli, such as *Enterobacter* and *Klebsiella* spp., and nosocomial gram-negative pathogens, such as *Pseudomonas aeruginosa* and *Serratia marcescens,* also are encountered. *Streptococcus pneumoniae* and *Haemophilus influenzae* are uncommon causal organisms. Infants with late-onset sepsis due to *S. pneumoniae* usually are term and have infection at 3 weeks of life or later.[16]

S. aureus is cause of healthcare-associated infection, accounting for 8% of late-onset infections in the NICHD NRN.[13] The incidence of late-onset MRSA infections increased by more than 300% among all birth categories between 1995 and 2004 according to data reported by the National Nosocomial Infections Surveillance (NNIS) system.[17] MRSA emerged as a cause of late-onset sepsis in neonates hospitalized in the neonatal intensive care unit (NICU) since birth.[18] MRSA strains from 75% of infants with late-onset BSIs due to *S. aureus* in one large NICU included MRSA USA300, the dominant clone in the United States. Outbreaks of MRSA neonatal pustulosis among term infants have been reported from many states.[19] Although the mortality rate is high among VLBW infants with invasive staphylococcal infections, BSIs due to MRSA and MSSA have equivalent morbidity and mortality rates.[20] Enterococci and *Candida* must be considered in infections that arise from the intestine or with use of intravascular devices. A national point-prevalence survey cited enterococci and fungi as the next most common bloodstream isolates after staphylococci in the NICU setting.[21]

Anaerobes and several unusual bacteria have caused infections in neonates.[22] Any bacterial isolate from blood or a normally sterile body site of a clinically ill neonate should be considered a true pathogen unless there is sufficient evidence to conclude that it is a contaminant.

Epidemiology

Systemic bacterial infections affect approximately 1 to 2 of 1000 liveborn neonates, with incidence inversely related to gestation. Characterized by age at onset, infections are called *early* or *late* (Table 92.2). The age at onset for early-onset bacterial infection is defined as 72 hours or less, usually with reference to neonates hospitalized in an intensive care unit compared with less than 7 days, often with reference to illness in term infants. The burden of early-onset sepsis in the United States is about 3300 cases annually; preterm and black infants are affected disproportionately.[23]

TABLE 92.2

Features Distinguishing Early-Onset From Later-Onset Bacterial Infection in Neonates

Feature	Early Onset[a]	Late Onset	Late, Late Onset
Time of onset (days of age)	≤3 or <7	>3 or ≥7–89	≥90
Maternal complications of labor or delivery	Common	Less common	Common
Incidence of prematurity	25%	Less common	Median birth weight <1000 g
Source of organism	Maternal genital tract	Maternal genital tract; nosocomial; community	Nosocomial; community
Usual clinical presentation	Nonspecific or respiratory distress	Nonspecific or focal	Nonspecific or focal
Mortality rate (%)	5–15	2–10	5–60

[a] The age at onset for early-onset bacterial infection is defined as ≤72 hours, usually

with reference to infants hospitalized in a neonatal intensive care unit or as <7 days, often with reference to illness in term infants.

Most infants with early-onset infection are ill at or within 48 hours of birth. Maternal obstetric complications are common, and the source of pathogens is the maternal genital tract. The typical clinical presentation is respiratory distress or nonspecific signs, often indistinguishable from noninfectious disorders, but without evidence of focal infection other than pneumonia. Among VLBW infants, early-onset sepsis does not increase the risk for late-onset sepsis.[24]

For infants with late-onset infection, maternal obstetric complications other than preterm delivery are uncommon. The incidence of infection is similar for singleton and multiple birth infants.[25] The source can be the maternal genital tract, the hospital environment if duration of hospitalization exceeds a few days, or the community. The usual clinical presentation is one of nonspecific signs but focal manifestations, such as skin or soft tissue infection, pneumonia, or meningitis, are more frequent than with early-onset infection.

The survival of VLBW or ELBW neonates has prompted the use of a third category: *late, late* or *very late* onset. Although these infants are strictly speaking no longer neonates, their median gestational age of less than 28 weeks at birth and their continuing hospitalization for postnatal complications accord them an extended interval as “newborns” on the basis of postmenstrual age. These infants almost always have devices (e.g., catheters) that can lead to infection by commensal species. The mortality rate ranges from 5% to 60%, depending on the infecting agent.

Pathogenesis

Infants who experience early-onset sepsis, especially preterm infants, often have one or more risk factors associated with their mother's labor and delivery (Table 92.3). Although term infants with early-onset sepsis can have associated maternal intrapartum complications, 50% to 70% of those with early-onset GBS sepsis have no identifiable maternal factors. Maternal factors enhancing risk for early-onset septicemia include preterm delivery, premature rupture of membranes (i.e., rupture of membranes before onset of labor at any gestation), prolonged rupture of membranes (>18 hours), chorioamnionitis, GBS bacteriuria during pregnancy, early postpartum febrile conditions (including maternal bacteremia, endometritis, and wound infection), and complications of delivery causing or associated with fetal hypoxia.

TABLE 92.3

Maternal Peripartum Risk Factors for Early-Onset Bacterial Infection

Risk Factor	Comment
Preterm delivery	Attack rate inversely related to gestation <37 wk
Premature rupture of membranes	Rupture of membranes >1 hr before onset of labor at any gestation
Chorioamnionitis[a]	Risk of neonatal septicemia is 5%–15%
Urinary tract infection	Higher neonatal risk even when mother asymptomatic
Multiple pregnancy	Only for group B streptococcal septicemia
Prolonged rupture of membranes	Attack rate directly proportional to duration of rupture of membranes >18 hr
Early postpartum febrile morbidity	Maternal fever (>38°C) during the first 24 hr postpartum
No prenatal care	Higher neonatal risk
Fetal hypoxia	Apgar score <6 associated with higher risk

[a] Chorioamnionitis or intrauterine amniotic infection when a strict definition is employed (i.e., maternal fever ≥38° C *plus* ≥2 of the following: maternal tachycardia [>100 beats/min], fetal tachycardia [>160 beats/min], peripheral white blood cell count >15,000 cells/mm^3, uterine tenderness, foul smelling lochia of amniotic fluid, and exclusion of maternal respiratory or urinary tract infection).

The pathogenesis of neonatal septicemia is multifactorial and encompasses microbial, host, metabolic, and environmental factors. Infants with exposure to a high maternal genital inoculum (>10^5 colony-forming units/mL) of GBS, for example, are at a greater risk for septicemia than those exposed to a maternal carrier who has low-density colonization. Compared with term infants, premature neonates are at increased risk of septicemia because of passive acquisition of lower levels of maternally derived total immunoglobulin G (IgG) and specific antibodies to bacterial pathogens; immature function of neutrophils and decreased neutrophil storage pools; and immature immune responses to pulmonary invasion and bacteremia. Decreased expression of lectin family proteins is an additional form of neonatal immunodeficiency.[26]

Metabolic factors such as hypoxia, acidosis, and hyperbilirubinemia further compromise host response. Interruption of mucosal or skin barriers by endotracheal or nasogastric tubes, intravascular access devices, blood sampling, and monitoring equipment promote bacterial invasion, particularly for late, late-onset infection. Prior therapy with broad-spectrum antimicrobial agents increases the likelihood that bacteria resistant to routinely employed antimicrobial regimens will cause late-onset infection.

Clinical Manifestations

Septicemia and Meningitis

The risk of bacterial infection in healthy-appearing neonates is low.[27] Clinical signs of bacterial infection, however, can be subtle, and even minimal deviation from usual activity can be the first indication of invasive infection (Table 92.4). In one series of 647 infants, hypoglycemia and hypothermia were the most common findings in cases of early-onset and late-onset sepsis.[2] In another report, hyperthermia was the most common sign among 455 neonates, but only one half of the infants had fever as a sign of septicemia.[22] Temperature elevation without infection in term infants is uncommon (except for fever associated with prostaglandin therapy). Only 1% of healthy infants have fever, defined as an axillary temperature in excess of 37.5°C to 37.8°C.

TABLE 92.4

Clinical Signs of Bacterial Infections in the Newborn

Clinical Sign	Frequency of Sign	
	Septicemia	Meningitis
Hyperthermia	+++	+++
Hypothermia	++	++
Respiratory distress	++	++
Apnea	+	+
Jaundice	++	++
Lethargy	++	+++
Anorexia or vomiting	++	++
Irritability	+	++
Convulsions	−	++
Bulging or full fontanel	−	++
Diarrhea or abdominal distention	+	+
Hypotension	++	+

+++, encountered in ≥50%; ++, frequently associated (25%–49%); +, occasionally observed (15%–24%); −, rarely associated (<15%).

Adapted from Nizet V, Klein JO. Bacterial sepsis and meningitis. In Wilson CB, Nizet V, Maldonado YA, et al. (eds). Remington and Klein's Infectious Diseases of the Fetus and Newborn Infant, 8th ed. Philadelphia: Elsevier Saunders; 2016, pp 217–271.

Infants with a temperature abnormality should be examined closely for other accompanying signs. One third to one half of infants with septicemia have signs of respiratory distress, including tachypnea and grunting. Among term infants returning for evaluation after the first week of life, jaundice can be a presenting feature. Findings such as lethargy, irritability, abdominal distention, and diarrhea are less common clues, occurring in less than one fourth of infants.

Neonates with meningitis generally have the same signs as those with septicemia (see Table 92.4). Seizures also occur in up to 50%, a bulging or full fontanel in up to 30%, and nuchal rigidity in approximately 15%. These signs suggest meningitis, but their absence does not exclude central nervous system infection.

Infants should be examined for signs suggesting foci of bacterial infection, including otitis media, conjunctivitis, pneumonia, cellulitis, and abdominal findings of distention and diminished bowel sounds. Necrotizing enterocolitis is associated with BSI in almost half of affected infants and is typically attributed to gram-negative bacilli.[28] Extremities should be examined for limitation of motion, swelling, warmth, erythema, and pain with palpation. The signs of osteomyelitis and pyogenic arthritis are subtle. Skin lesions, including pustular lesions consistent with staphylococcal infection, should be sought.

Acute Otitis Media.

Healthy term infants have otoscopic findings in the immediate neonatal period (e.g., diminution or absence of mobility, a pink appearance) that would suggest middle ear inflammation in an older infant. These features are progressively less common by age 1 month. For most neonates, a diagnosis of AOM is established presumptively with pneumatic otoscopy and confirmed by tympanocentesis.[29] Common presenting features are respiratory signs and fever.[30] The usual pathogens are *S. pneumoniae* and *H.*

influenzae; gram-negative bacilli, and *S. aureus*, each comprising less than 10% of isolates.

Conjunctivitis.

Infectious conjunctivitis in neonates is caused by *Chlamydia trachomatis* and various gram-positive and gram-negative bacteria, including *S. aureus, S. pneumoniae, Enterococcus,* and *Haemophilus* spp.[31] *Neisseria gonorrhoeae,* herpes simplex virus, and adenovirus are infrequent but important pathogens. Regardless of the pathogen, eyelid edema, hyperemia of the palpebral conjunctivae, and purulent discharge are common findings. Findings frequently are bilateral. Hospitalized ELBW infants are more likely to have gram-negative enteric bacteria causing conjunctivitis compared with higher birth weight NICU infants.[32]

Osteomyelitis and Pyogenic Arthritis.

Two clinical syndromes are associated with bone or joint infection in neonates (Table 92.5). The mild or subacute form is a consequence of low-grade and transient bacteremia. Edema and swelling of the extremity or joint, usually without warmth or erythema, can occur for several weeks before the diagnosis. Typically, pain is elicited by moving the infant during diaper or clothing changes. Spontaneous movement is decreased in the involved extremity, a consequence of pain (i.e., pseudoparalysis) or weakness. This presentation is typical of GBS. Erb palsy sometimes is diagnosed erroneously when the proximal humerus is involved.

TABLE 92.5

Clinical Presentation of Bone and Joint Infections in Newborn Infants

Manifestation	Mild Form	Severe Form
Preceding bacteremia	Low-grade or transient	Prolonged or intense
Duration of signs	Can be several weeks	Simultaneously with bacteremia or in days after initiation of therapy
Physical findings	Subtle	Prominent
Multiple bone involvement	Uncommon	Common

The severe presentation is a consequence of a prolonged or intense BSI. Staphylococci, including MRSA or MSSA, are the usual pathogens. Severe systemic signs overshadow early localizing signs of hematogenous seeding of bones. Bone or joint foci can be seen concurrently with a BSI or days after initiation of therapy. Inflammatory changes, such as swelling, tenderness, erythema, and warmth, are prominent. Because of spread across transphyseal vessels, infection in the metaphysis spreads to the contiguous epiphysis and into the joint.[33]

The presenting signs of osteomyelitis in 121 neonates consisted of swelling in 64%, pseudoparalysis in 55%, tenderness in 32%, erythema in 30%, fever in 45%, and irritability or lethargy in 36%.[34] Common sites of infection are the femur, humerus, and tibia. Cuboidal bones, primarily bones of the hands or feet, and the flat bones of the ribs, skull, sternum, and scapula account for one fourth of sites. Osteomyelitis due to *Serratia marcescens* should raise suspicion for chronic granulomatous disease as an underlying condition.[35] Infants with osteomyelitis due to *Candida* spp. have a similar presentation, with subtle signs and sometimes involving multiple sites; *Candida* osteomyelitis has become rare if there is early institution of therapy and rapid control of BSI.

Skin and Soft Tissue Infections.

Skin or soft tissue foci infection can lead to BSI. Pustular lesions can be a presenting feature of staphylococcal BSI, more often with *S. aureus* than with CoNS. Other skin manifestations of infection in the neonate include cellulitis, abscess, impetigo, omphalitis, and necrotizing fasciitis.[16,18,36] They usually are a consequence of gram-positive infection, especially *S. aureus,* but gram-negative bacteria should be considered until excluded by culture. Occasionally, infection due to *Candida* spp. can manifest as soft tissue abscesses.

Laboratory Findings and Diagnosis

Septicemia Screening Tests

The difficulty in early diagnosis of bacterial infection in neonates has prompted investigation of a number of screening tests. However, no single biomarker or panel is sufficiently sensitive to obviate evaluation of infants with clinical signs of illness.[37,38] Taken in the context of limitations, the total white blood cell (WBC) count with a differential leukocyte count and other screening tests (Table 92.6) can be moderately useful in sepsis screening and in minimizing the duration of antibiotic exposure.[39]

TABLE 92.6

Screening Tests for Septicemia: Uses and Limitations

Test Finding	Finding Supporting Possible Infection	Comments
Total white blood cell count (cells/mm^3)	<5000	High likelihood ratio when test performed at ≥4 hr of life
Absolute neutrophil (polymorphonuclear [PMN]) count (cells/mm^3)	<1000	High likelihood ratio when test performed at ≥4 hr of life
Total immature PMN count (cells/mm^3)	>1100 (cord blood) >1500 (12 hr) >600 (>60 hr)	Relatively insensitive; finding unusual in uninfected infants
Ratio of immature PMNs to total PMNs	>0.2	Sensitivity 30%–90%; good negative predictive value
Platelet count (cells/mm^3)	<100,000	Insensitive, nonspecific, and late finding
C-reactive protein (mg/dL)	>1	Sensitivity 50%–90% at onset
Interleukin-6 (pg/mL)	>15	Sensitivity >80%; cutoff points vary; serial determinations may be required
Interleukin-8 (pg/mL)	>18	High sensitivity and negative predictive value
Procalcitonin (ng/mL)	>0.5	Promising for early- and late-onset infection
Erythrocyte sedimentation rate (mm/hr)	>5 (first 24 hr) > Infant's age in days + 3 (through age 14 days) >20 (>2 wk of age)	Individual laboratories must establish normal values; normal value varies inversely with hematocrit
Fibronectin (μg/mL)	<120–145	Sensitivity 30%–70%
Serum amyloid A (mg/dL)	>0.8–1.0	High sensitivity and negative predictive value; commercial kit available

A retrospective cross-sectional study of more than 67,000 term and late preterm newborns who had complete blood cell (CBC) count and blood culture obtained within 1 hour of each other for newborns younger than 72 hours of age determined that optimal interpretation of the CBC count requires using interval likelihood ratios according to the newborn's age in hours.[40] The WBC and absolute neutrophil counts were most informative when they were low and when testing was performed at 4 hours of age or later. A normal WBC count does not exclude bacterial BSI, especially in VLBW neonates, but serial assessment of neutrophil values can predict the absence of early-onset sepsis.[41,42]

The C-reactive protein (CRP) level has a high sensitivity for diagnosing infection, but it can be elevated in many noninfectious conditions (e.g., respiratory distress syndrome, hypoxia, intraventricular hemorrhage, surgery) associated with tissue injury or inflammation, limiting its value as a screening test.[43,44] Procalcitonin is an acute phase reactant produced by monocytes and hepatocytes; expression increases several hours after exposure to bacterial endotoxin, and levels remain elevated for at least 24 hours. The utility of elevated procalcitonin level is limited by its rapid postnatal endogenous increase.[38,43,44]

Neutrophil CD64 expression increases when neutrophils are activated by infectious stimuli. The neutrophil CD64 index appears to have a high sensitivity and high negative predictive value for bacterial sepsis.[45,46] Mass spectrometry-based proteomic profiling offers promise in identifying signature host-response biomarkers relevant in neonatal infection.[47]

Microbiologic Techniques

Blood culture is the gold standard for the diagnosis of BSI. The desired volume of 0.75 to 1 mL has a sensitivity of approximately 90%. Multiple blood cultures only modestly increase sensitivity and can delay initiation of therapy.[48] Documentation of BSI is absent for approximately 10% of infants with clinical signs, and infection is presumed by the clinical course.

It is appropriate to initiate empiric antimicrobial therapy after an evaluation for sepsis. Meningeal drug dosing should be employed for neonates with suspected BSI until cerebrospinal fluid (CSF) is examined and meningitis is excluded. With computer-assisted automated blood culture systems, virtually all cultures containing clinically relevant bacteria are positive by 24 to 36 hours of incubation, and cultures containing CoNS or *Candida* spp are positive within 48 hours.[49] Antibiotic therapy should be discontinued if an infant has a benign clinical course and culture results are negative at 36 to 48 hours.

A lumbar puncture should be considered in all neonates evaluated for sepsis. If deferred because of clinical instability, CSF should be examined as soon as the infant's condition permits. In the era of intrapartum antibiotic prophylaxis, 20% of infants with GBS meningitis have sterile blood cultures.[50] Because the yield of lumbar puncture is low among healthy-appearing term neonates evaluated because of maternal risk factors and premature infants with respiratory distress, some experts omit lumbar puncture in evaluating such neonates. Wiswell and colleagues[51] observed that meningitis would have been missed or the diagnosis delayed in up to one third of neonates younger than 7 days of age if CSF had not been assessed. Weighing the benefits of early diagnosis against the minimal procedural risk, it is our practice to examine CSF in all neonates evaluated for early- and late-onset sepsis.

Urine culture is not required when evaluating infants with possible early-onset infection. Bladder tap or catheter-obtained urine should be obtained for culture for infants older than 6 days of age. Cultures from foci of clinically apparent infection are obtained for Gram stain and culture. Examples are purulent drainage from the eye, joint fluid or metaphyseal bone aspirate for suspicion of osteoarthritis, peritoneal fluid, and purulent material from pustules or soft tissue abscesses.

Cultures from surface sites or mucous membranes are not helpful. Isolates from sites such as the ear canal, nasopharynx, axilla, umbilicus, groin, rectum, stomach, and endotracheal tube are uncommonly the same as those from blood, CSF, or other sterile sites and have a positive predictive value of less than 10%.[52] Positive cultures from the placenta or gastric aspirate indicate exposure to a potential pathogen. Positive cultures from placenta or surface specimens do not dictate further evaluation if an infant has no signs or risk factors predisposing to septicemia.

Management: Empiric and Definitive Therapy

The choice of empiric antimicrobial therapy is influenced by likely etiologic agents, susceptibility patterns of isolates from infants in the NICU, the antimicrobial agent's CSF penetration, potential toxicity, and the infant's hepatic and renal function. Dosage schedules by age and weight should be available and used for agents selected.

Empiric Therapy

Early-Onset Sepsis.

Empiric therapy for early-onset sepsis, unchanged after 4 decades of use, consists of ampicillin in combination with gentamicin. After meningitis is excluded, ampicillin and gentamicin at the doses shown in Table 92.7 are employed. Gentamicin serum levels are not required unless therapy is given for more than 72 hours, renal function is abnormal or unstable, or birth weight is less than 1500 g. A 10-year retrospective review found that more than 90% of isolates from cases of culture-proven early-onset sepsis in term or late preterm infants were susceptible to ampicillin or gentamicin, or both.[53] Most nonsusceptible isolates were *S. aureus*, and infants had an uncomplicated course when therapy was modified appropriately.

TABLE 92.7

Empiric Antimicrobial Therapy for Neonatal Bacterial Infections

Clinical Presentation	Antibiotics (dose/kg, IV)	Frequency (hr)	Expected Duration (days)
Septicemia			
Early-onset (term infant)	Ampicillin (50 mg) *plus* gentamicin (4 mg)	q8 + q24[a]	10
Late-onset (term infant readmitted)	Ampicillin (75 mg) *plus* gentamicin (4–5 mg) or cefotaxime (50 mg) until meningitis excluded; then ampicillin (50 mg) q6	q6 + q24[a] or q 8	10
Late-onset (inpatient)	Vancomycin (15 mg)[b] *plus* gentamicin (5 mg) or amikacin (15–17.5 mg)	q36[a] or q24	10–14
Meningitis			
Early-onset	Ampicillin (100 mg) *plus* gentamicin (4 mg) *plus* cefotaxime (50 mg)	q8 + q8[a] q12	14–21
Late-onset	Ampicillin (75 mg) *plus* gentamicin (4–5 mg) or amikacin (15–17.5 mg) *plus* cefotaxime (50 mg)	q6 + q24[a] or q24[c] q8	14–21
Bone or joint infection	Vancomycin[b] *plus* gentamicin (4–5 mg)	q24[a]	3–6 wk
Suspected gastrointestinal infection	Include clindamycin (5 mg) or piperacillin-tazobactam (100 mg piperacillin component) *plus* aminoglycoside	q6–12 q8–12	10–14

[a] For age ≤7 days and body weight ≥2 kg, gentamicin dose is 4 mg every 24 hr; for age ≤7 days and body weight <2 kg, gentamicin dose is 5 mg/kg every 48 hr; for age 8–28 days and body weight >2 kg, gentamicin dose is 4–5 mg/kg every 24 hr; for age 8–28 days and body weight ≤2 kg, gentamicin dose is 5 mg/kg every 36 hr. Serum levels should be monitored if administered for >2 doses to achieve a peak of

5–10 µg/mL and a trough of <1.5 µg/mL.

[b] Dosing algorithm for vancomycin is based on serum creatinine level that reasonably reflects neonatal renal function at approximately 5 days after birth; if <0.7 mg/dL, the dose is 15 mg/kg every 12 hr; if 0.7–0.9 mg/dL, the dose is 20 mg/kg every 24 hr; if 1–1.2 mg/dL, the dose is 15 mg/kg every 24 hr; if 1.3–1.6 mg/dL the dose is 10 mg/kg every 24 hr; if >1.6 mg/dL the dose is 15 mg/kg every 48 hr.

[c] Serum levels should be monitored to achieve an amikacin peak of 20–35 µg/mL and a trough of <10 µg/mL.

Use of maternal intrapartum antibiotic prophylaxis for prevention of early-onset GBS infection has raised concern about increasing ampicillin resistance among *E. coli* isolates. Results of a nationally representative sample published in 2002 indicated that the proportion of *E. coli* infections resistant to ampicillin increased only among preterm infants.[54] In a later study, intrapartum ampicillin exposure was not associated with an increase in the incidence of ampicillin-resistant early-onset sepsis over 18 years.[55]

Including a third-generation cephalosporin for the empiric treatment of presumed meningitis is advisable. Some experts advocate substitution of cefotaxime for gentamicin for empiric treatment of presumed nonmeningeal early-onset infection in neonates. This is inadvisable for the following reasons: superior efficacy compared with ampicillin plus gentamicin has not been demonstrated; third-generation cephalosporins are not active against *Listeria* or *Enterococcus* spp.; routine use of these agents exerts selective pressure for colonization with and BSI caused by multidrug-resistant gram-negative organisms[56]; and for NICU patients, the concurrent use of ampicillin and cefotaxime within the first 3 days of life is associated with an increased risk of death compared with the use of ampicillin and gentamicin.[57]

Late-Onset Sepsis.

For the term infant up to 8 weeks of age who is readmitted to the hospital for possible septicemia without an apparent focus of infection, ampicillin plus gentamicin or ampicillin plus cefotaxime is appropriate for empiric therapy unless *S. aureus* infection is suspected. For skin, soft tissue, and bone and joint infection, vancomycin is substituted for ampicillin. For meningitis, cefotaxime is given in addition to ampicillin plus gentamicin or instead of gentamicin. For infection of suspected gastrointestinal origin, clindamycin or another agent active against anaerobes (i.e., metronidazole) should be included. For infants previously treated with gentamicin, amikacin could be substituted, but gentamicin-resistant organisms are uncommon outside of NICU outbreak settings.

Definitive Therapy

Definitive therapy is based on the susceptibility of the isolated pathogen. Suggested duration of therapy is summarized in Table 92.7. The drug of choice for invasive GBS infection is penicillin (see Chapter 119). Infants with ampicillin-susceptible *E. coli* BSI can receive ampicillin monotherapy. For ampicillin-resistant isolates, an aminoglycoside or cefotaxime is appropriate for treatment. Combination therapy with a β-lactam agent plus an aminoglycoside can be considered for BSI caused by *Enterobacter*, *Serratia*, or *Pseudomonas*. Infants with BSI caused by extended-spectrum, β-lactamase–producing, and multidrug-resistant gram-negative organisms should receive meropenem.[58]

Topical mupirocin has been used for mild cases of neonatal staphylococcal pustulosis. For localized pustulosis in a preterm or VLBW infant or for more extensive disease in term infants, vancomycin administered parenterally is recommended, at least until a BSI is excluded.[59] Therapy for MSSA infections can be completed with nafcillin. Vancomycin is the drug of choice for MRSA sepsis and for associated bone and joint infections. Limited experience indicates that linezolid is well tolerated and is as effective as vancomycin in treatment of resistant gram-positive infections in neonates.[60]

Infants with meningitis typically have progression of clinical illness after antimicrobial therapy is initiated, and observation under intensive care is recommended for a minimum of 24 hours. Bactericidal agents should be chosen, and for gram-negative bacillary meningitis, concurrent use of two active agents (e.g., cefotaxime plus gentamicin) is ideal. Doses used should be high enough to achieve bactericidal concentrations in the CSF but to avoid associated toxicity (see Table 92.7).

After the pathogen has been identified, antimicrobial susceptibility determined, and the CSF proved to be sterile, therapy is modified to the most active, narrow-spectrum agents with the least toxicity. The drugs of choice are penicillin G alone (450,000–500,000 units/kg/day) for GBS and ampicillin (300 mg/kg/day) for *L. monocytogenes*. For enteric pathogens, the first 7 days of treatment consists of a β-lactam agent plus an aminoglycoside. Some exceptions occur, such as ampicillin-susceptible *E. coli* or *Proteus mirabilis* meningitis, for which ampicillin alone is efficacious. Meningitis due to multidrug-resistant gram-negative bacilli necessitates the use of meropenem.

Failure of antibiotic therapy to sterilize the CSF within 24 to 36 hours suggests focal involvement, such as cerebritis, ventriculitis (often with obstruction), subdural empyema, or early abscess formation. For meningitis caused by GBS, therapy is administered for a total of 14 to 21 days; for *L. monocytogenes,* 14 days is recommended; and for enteric bacilli, 14 days after sterilization of CSF or 21 total days (whichever is longer) is indicated. For optimal management, sterility of CSF should be documented at 24 to 48 hours after initiation of therapy. The diagnosis of meningitis in the neonate mandates supportive care not routinely given to infants with septicemia, such as careful observation for and control of respiratory failure and seizures, fluid administration with consideration of potential inappropriate secretion of antidiuretic hormone secretion, and care that minimizes elevation of intracranial pressure.

Prognosis and Sequelae

Infection in VLBW infants adversely affects their outcomes. VLBW infants with infection during their hospitalization are significantly more likely than are those without infection to have impaired neurodevelopmental outcomes in early childhood, including cerebral palsy.[61] For ELBW infants, antenatal exposure to chorioamnionitis, particularly histologically confirmed plus clinical chorioamnionitis, compared with no exposure also is associated with an increased risk of cognitive impairment.[62]

The outcome for neonatal bacterial meningitis is guarded, regardless of birth weight and age at onset. Among infants surviving an episode of GBS meningitis, 22% have neurologic sequelae at hospital discharge, including persistent seizures, hypertonicity, and dysphagia.[63] Among 88 term or near-term survivors of meningitis in one report, 17 had moderate or severe disability at 1 year of age.[64] In a report comparing 5-year outcomes, more children surviving neonatal meningitis had serious disability (23%) than children from a general pediatric practice (2%).[65]

Recent Advances

Ongoing morbidity and mortality from neonatal sepsis despite the use of potent antimicrobial agents and advances in critical care medicine have prompted interest in early pathogen identification through tools such as multiplex polymerase chain reaction (PCR), multiplex pyrosequencing PCR assays, and matrix-assisted laser desorption/ionization–time of flight (MALDI-TOF) mass spectrometry to identify pathogens directly from whole blood. Real-time PCR and pyrosequencing of the universal 23S rRNA gene has been used successfully in testing neonatal blood culture samples.[66]

Efforts are ongoing to define more efficient strategies for evaluation and treatment of early-onset sepsis in term and late preterm infants. Risk assessment based only on objective clinical data available at birth has been proposed.[67] An accurate multivariate predictive model of sepsis has been developed for infants born at 34 weeks' gestation or later.[68] Escobar and colleagues[69] conducted a retrospective, nested case-control study combining objective maternal data with evolving neonatal clinical findings. A risk stratification scheme that divided the neonatal population into groups treated empirically, those observed and evaluated, and those managed by continued observation was proposed that could result in substantially decreased antibiotic treatment. Prospective evaluation is required to determine the feasibility of using such a model to guide clinical decision making.

Results of clinical trials evaluating adjunctive therapies have become available. A large, randomized, multicenter, placebo-controlled trial found that therapy with immune globulin intravenous (IGIV) did not reduce neonatal sepsis deaths or major disabilities at 2 years of age.[70] Routine administration of IGIV in suspected or documented neonatal bacterial infection is not recommended.[71] A multicenter trial (i.e., PROGRAMS trial) found that early postnatal prophylactic granulocyte-macrophage colony-stimulating factor corrected neutropenia in ELBW infants but did not reduce the incidence of sepsis or improve outcomes.[72]

The impact of intestinal microbiota composition on prevention of neonatal sepsis is being investigated, as is the potential for promotion of gut microbiome diversity through administration of probiotics. Antibiotic use perinatally and during in the first week of life has sustained effects on the gut microbiota of preterm infants, increasing the relative abundance of *Enterobacter* or the Enterobacteriaceae family of organisms and lowering bacterial diversity.[73,74] Dysbiosis caused by antibiotic use can precede and potentially precipitate sepsis and necrotizing enterocolitis. Use of probiotics to colonize the premature gut and normalize the fecal microbiota can potentially prevent bacterial infections.[73] Prospective, controlled clinical trials based on these hypotheses are needed.

Prevention

Three general approaches for the prevention of neonatal septicemia have been suggested, and the first two have been efficacious: improvement in prenatal care resulting in delivery of infants at term gestation and without maternal risk factors for septicemia, maternal intrapartum antibiotic prophylaxis for prevention of early-onset GBS septicemia, and maternal immunization to provide pathogen-specific, IgG-mediated passive immunity for the infant.

Although the first approach, provision of prenatal care, especially for women younger than 20 years, is self-evident, its achievement continues to elude even urban centers. A decline in the rate of preterm deliveries can reduce the incidence of neonatal septicemia and would eliminate most very-late-onset BSIs and healthcare-associated infections in NICUs. The second approach, intrapartum antibiotic prophylaxis, targets women who are antenatally identified as carriers of GBS to prevent early-onset neonatal GBS septicemia. Sepsis caused by other organisms is more often associated with preterm birth.[75] Implementation of intrapartum antibiotic prophylaxis has been associated with an 85% decrease in the incidence of early-onset GBS infection[3] (see Chapter 119).

Whereas intrapartum antibiotic prophylaxis is a desirable interim approach, prevention of all GBS infections, irrespective of age at onset or presence of maternal risk factors, awaits availability of suitable maternal vaccines. Candidate capsular polysaccharide-protein conjugate vaccines are in development. If efficacy can be documented, women can be immunized to protect their neonates against early- and late-onset GBS disease. This approach also could be successful in prevention of infection caused by other neonatal pathogens.

Key Points

Diagnosis and Management of Bacterial Infections in the Neonate

Epidemiology

- Bacterial infections affect 1 or 2 of every 1000 live births, with a mortality rate in developed countries of 5% to10%.
- Early-onset disease manifests signs of illness within the first hours to a few days of life, often in association with maternal obstetric complications.
- Late-onset infection, variously defined as occurring at 4 days or 7 days of life or older, can have focal manifestations.
- Clinical features typically are nonspecific in early- and late-onset disease.
- Common causes of early-onset infection are group B *Streptococcus* (GBS) and *Escherichia coli.*
- Common causes of late-onset infection are coagulase-negative staphylococci, gram-negative enteric bacilli, *Staphylococcus aureus*, and GBS.

Diagnosis

- Isolation of a pathogen from blood or a normally sterile site, such as cerebrospinal fluid, establishes the diagnosis.
- No single biomarker or panel of tests has sufficient positive or negative predictive value to provide an unequivocal diagnosis.

Treatment

- Empiric antimicrobial agents, broadly targeting gram-positive and gram-negative pathogens, are employed in suspect cases while awaiting culture results.

- Definitive therapy targets the infecting microorganism.

- The recommended duration of treatment is 10 days for sepsis and 14 to 21 days for meningitis.

Prevention

- Intrapartum antibiotic prophylaxis has been associated with a significant reduction in early-onset GBS disease.

- Maternal immunization holds promise for prevention of GBS in neonates and young infants.

Viral Infections in the Fetus and Neonate

Robert F. Pass, Swetha Pinninti

Neonates, like older children and adults, are subject to viral infections acquired by horizontal routes, such as those due to influenza, rotavirus, and enteroviruses. They also are at risk for viruses through routes that are unique to the perinatal setting in which mother-to-child transmission can occur transplacentally, during birth, or from breast milk. The ability of cytomegalovirus (CMV), herpes simplex virus (HSV), human immunodeficiency virus (HIV), and human T-lymphotrophic virus type 1 (HTLV-1) to establish chronic infection in the mother with persistence of infectious virus in blood, mucosa, or milk accounts for the role vertical transmission plays in their epidemiology and potential clinical impact.

Whether viruses that produce acute, self-limited infections in the mother are transmitted to the fetus or newborn depends on the timing of maternal infection in relation to gestation and parturition. The clinical settings in which fetal and neonatal viral infections must be considered include pregnancy, the newborn nursery, and the evaluation of an ill newborn.

This chapter provides an overview of the viral infections that occur in these settings. Detailed discussions of epidemiology, diagnosis, treatment, and prevention are presented in the chapters focused on specific viruses.

Pathogenesis

Viral infection of the fetus probably follows maternal secondary viremia or viral replication in the placenta. Developmental immaturity of fetal and neonatal innate and adaptive immune function is important in pathogenesis.[1] The innate immune system and transplacentally transferred maternal antibodies are the first line of defense against viral infections because the fetus and newborn have little or no prior experience to prime adaptive immune responses. Their adaptive immune systems are slow to respond compared with adults. Fetal and neonatal antigen-presenting cells (i.e., monocytes and dendritic cells) have reduced functionality compared with cells from adults.

Toll-like receptors (TLRs) and natural killer (NK) cells are key components of the innate immune system. NK cells have the ability to lyse virus-infected cells, and they are important sources of interferon γ (IFγ). IFγ can inhibit viral replication directly and enhance innate and adaptive immune responses.

TLRs recognize distinct features of viruses (e.g., nucleic acids), triggering induction of cytokine production and proinflammatory pathways that activate NK cells. TLRs also play a key role in increasing cell surface expression of major histocompatibility complex (MHC) class II molecules and costimulatory molecules CD40, CD80, and CD86 on the surface of plasmacytoid dendritic cells, which leads to activation of adaptive immunity, including cytotoxic T lymphocytes and B lymphocytes.[2] TLR stimulation of newborn antigen-presenting cells results in deficient production of tumor necrosis factor and IFγ and a predominantly anti-inflammatory cytokine profile compared with adults.

NK cells from newborns have an immature phenotype, decreased cytolytic ability, and markedly decreased production of IFγ compared with adults. Newborns also have higher proportions of circulating myeloid cells with a neutrophil phenotype that suppress T-lymphocyte proliferation, cytokine secretion, and NK cell cytotoxicity.

Maternal antibody acquired transplacentally and antibody and immunocompetent cells present in colostrum and mother's milk are important components of the neonate's defense against viral infection. A neonate infected by a virus to which the mother lacks immunity is prone to severe infection; neonatal infections caused by herpesviruses are illustrative. Transfusion-acquired CMV infection rarely is evident clinically in term infants of seropositive mothers, but it can cause severe illness in small, antibody-negative premature infants. HSV and varicella-zoster virus (VZV) are more likely to cause severe disease in the neonate with absent or low concentrations of maternal antibodies.

Epidemiology

Virus Transmission From Mother to Child

Viruses for which mother-to-child transmission has well-characterized clinical consequences are listed in Table 93.1. Whether maternal viral infection is spread to the fetus or neonate is determined by the occurrence of viremia, exposure to virus during labor and delivery, or from virolactia. For many viruses, the prevalence of infection among women of childbearing age and the incidence of new infections during pregnancy contribute to the overall prevalence of fetal or neonatal infection. Transmission of VZV, rubella virus, parvovirus B19, hepatitis E virus, and several agents not listed in Table 93.1 is based on the incidence and timing of maternal infection in relation to pregnancy and delivery. Rates of maternal infection due to viruses are listed in Table 93.1. The risk of transmission and the consequences of infection for the fetus or newborn are described elsewhere in this textbook.

TABLE 93.1

Viruses for Which Mother-to-Child Transmission Has Well-Characterized Clinical Consequences

Virus	Clinical Features	Transmission Route[a]
Chikungunya virus	Fever, sepsis, encephalopathy	Transplacental, intrapartum
CMV	Congenital infection syndrome	Transplacental
Dengue virus	Fever, rash, hepatosplenomegaly, thrombocytopenia, pleural effusion	Transplacental, intrapartum
Hepatitis B virus	Chronic liver disease	Intrapartum

Hepatitis C virus	Chronic liver disease	Intrapartum
Hepatitis E virus	Jaundice, hepatitis, liver failure	Transplacental, intrapartum?
HSV	Neonatal herpes	Intrapartum
HIV	Perinatal HIV/AIDS	Intrapartum, breast milk
Human papillomavirus	Laryngeal papillomatosis	Intrapartum
HTLV-1	Adult T-cell leukemia	Breast milk
LCMV	Encephalopathy, chorioretinitis	Transplacental
Parvovirus B19	Anemia, hydrops	Transplacental
Rubella virus	Congenital rubella syndrome	Transplacental
Zika virus	Microcephaly and other anomalies	Transplacental

[a] Principal route responsible for clinical consequences.

AIDS, acquired immunodeficiency syndrome; CMV, cytomegalovirus; HSV, herpes simplex virus; HIV, human immunodeficiency virus; HTLV-1, human T-cell lymphotrophic virus; LCMV, lymphocytic choriomeningitis virus.

Mother-to-child transmission of some viruses not listed in Table 93.1 is known to occur. Studies of GB virus C (i.e., hepatitis G virus), a hepatotrophic flavivirus that produces chronic infection, show that 60% to 80% of infants born to mothers with viral RNA in their blood are infected. Transiently elevated serum alanine aminotransferase concentrations have been found, but no illness in infants has been associated with perinatal infection.[3] Zika virus, a member of the flavivirus family that is transmitted by the *Aedes aegypti* mosquito, can be transmitted transplacentally and has been associated with microcephaly and central nervous system damage.[4–6] Sporadic reports of congenital disease due to enteroviruses or adenovirus and detection of viral nucleic acid by polymerase chain reaction (PCR) testing of amniotic fluid suggest that transplacental transmission of these viruses may be more common than appreciated.[7–9]

Infection of the newborn at birth occurs through exposure to virus in the genital tract or perineum; it is the major route of acquisition of HSV, HIV, hepatitis B, and hepatitis C. Labor and delivery prolong the contact between the neonate's mucosal surfaces and maternal surfaces, secretions, and blood, facilitating the transfer of viruses. The newborn who acquires virus during birth typically becomes viremic or sheds virus in other body fluids within days to a few months postpartum. Intrapartum acquisition of HSV and HIV has well-known clinical consequences. Acquisition of hepatitis B and hepatitis C lead to chronic infection that can progress to chronic hepatitis, cirrhosis, and hepatocellular carcinoma. Intrapartum acquisition of CMV is common, but infection usually is not clinically significant except in a small proportion of very low birth weight premature infants.

Mother-to-child transmission of viruses through human milk is important in the epidemiology of CMV, HTLV-I, and HIV. The nursing infant is exposed to this potential source of infection many times each day for months. Breastfeeding is the major route for infant acquisition of CMV, which rarely causes acute illness and is not associated with adverse sequelae. In populations with high rates of maternal seropositivity and breastfeeding, most infants acquire CMV during the first year of life.[10] Breast milk–acquired CMV infection in very low birth weight premature newborns is a possible exception (see Chapter 206).

HIV and HTLV-I can be transmitted through human milk; the onset of infection usually is after 1 month of age.[11–13] Breast milk also may be the source of GB virus C and torque teno virus, but neither has been proved to cause disease when transmitted through human milk.[3,14] Perinatal transmission likely involving breastfeeding has been reported for rubella virus, HSV, echovirus 18, dengue virus, West Nile virus, and Zika virus.[15–19] Viruses that are transmitted through blood can be transmitted during breastfeeding in the setting of bleeding or cracked nipples.

Because of the association of higher infant mortality with formula feeding, the potential transmission of maternal viral infection rarely should be a reason to interdict breastfeeding in developing countries, with the possible exception of HIV infection. In the context of maternal HIV infection, the 2010 World Health Organization guidelines on infant feeding recommend that national authorities in each country decide which infant feeding practice should be supported.[20] The previous recommendation that "…replacement feeding should not be used unless it is acceptable, feasible, affordable, sustainable, and safe" remains, but stronger support is stated for maternal antiretroviral treatment and continued breastfeeding, especially in countries where not breastfeeding is associated with increased infant mortality and rates of mother-to-child transmission of HIV are high. In 2013, the American Academy of Pediatrics (AAP) Committee on Pediatric AIDS reiterated its recommendation for the United States of complete avoidance of breastfeeding "…regardless of maternal viral load and antiretroviral therapy."[21] The AAP's 2015 guidance is summarized in Table 93.2.[22]

TABLE 93.2

Prevention of Transmission of Viruses Through Human Milk in the United States

Virus	Recommendation
Cytomegalovirus	Risk for only very low birth weight preterm; no clear recommendation
Hepatitis B virus (HBV)	Administer first dose of HBV vaccine and hepatitis B immune globulin within 12 hours of birth; no restriction on breastfeeding after immunization.
Hepatitis C virus	Not a contraindication to breastfeeding. Abstain from breastfeeding if nipples are cracked or bleeding.
Herpes simplex virus	Avoid any contact between baby and herpetic lesions. Use good hand hygiene. Avoid nursing from an affected breast until lesions are resolved.
Human immunodeficiency virus	Do not breastfeed.
Human T-lymphotrophic virus I	Do not breastfeed.
Human T-lymphotrophic virus II	Do not breastfeed.
Rubella	Neither acute rubella nor recent receipt of rubella vaccine is a reason to avoid breastfeeding.
Varicella	Follow age-based recommendations for administration of hyperimmune globulin; no recommendations regarding breastfeeding.
West Nile virus	Breastfeeding is recommended in endemic area; no recommendation for acute infection during lactation.

From Kimberlin DW, Brady MT, Jackson MA, Long SS (eds). The Red Book: 2015 Report of the Committee on Infectious Diseases, 30th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2015, pp 128–131.

Sources of Maternal Infection

The risk of maternal infection is related to the epidemiology of the specific virus and type of exposure. CMV infection is common among young children who shed CMV chronically. Exposure to young children is probably the most important risk factor for maternal CMV infection. Sexual activity is a risk factor for HSV, CMV, HIV, and hepatitis B virus infection. Injecting drug use is a risk factor for HIV, hepatitis B virus, and hepatitis C virus. For viruses that cause acute, self-limited infections with seasonal or periodic epidemics such as parvovirus B19, rubella, and enteroviruses, risk of maternal and congenital infection is related to epidemic activity in the community. Endemic rubella and congenital rubella have been eliminated from the United States and the Region of the Americas through the widespread use of rubella vaccine.

Animal and insect vectors can be the source of maternal viral infections that are spread to the fetus or newborn. Congenital infection due to lymphocytic choriomeningitis virus (LCMV) is likely underdiagnosed in the United States. Maternal LCMV infection, especially in the first trimester, can lead to fetal infection with subsequent chorioretinitis, microcephaly or macrocephaly, and intracranial calcifications. Maternal exposure to rodents may be the key epidemiologic clue.[23,24] West Nile virus is an arthropod-borne pathogen with transplacental and breast milk transmission reported in the United States.[25,26] However, mother-to-child transmission appears to be rare. Dengue virus, chikungunya virus, and Zika virus are transmitted to humans by *A. aegypti* mosquitoes and cause similar acute febrile illnesses. Maternal chikungunya virus infection can be transmitted to the fetus and neonate; a transmission rate of almost 50% has been reported with maternal viremia at term.[27]

Although it is unclear whether maternal infection affects the outcome of pregnancy, newborn infection can manifest as sepsis and encephalopathy, often associated with central nervous system sequelae.[27,28] Dengue virus infection is common in tropical areas, and rates of mother-to-child transmission range from 12% to 60% when infection occurs during pregnancy. Similar to chikungunya virus infection, maternal dengue viremia at term is associated with neonatal infection that can manifest as sepsis with fever, thrombocytopenia, hepatosplenomegaly, rash, and pleural effusion.[29]

Community-Acquired and Nosocomial Postnatal Infection

Horizontal transmission of viruses to neonates from caregivers or family members occurs primarily through infected droplets or contaminated hands. Neonates are more vulnerable than older hosts because they are immunologically naïve and their care requires repeated handling and close contact. Outbreaks of many viruses in newborn nurseries have been described; enterovirus, adenovirus, rotavirus, and RSV are notable because they are common, are difficult to control, and have substantial clinical consequences.[6,30] Neonates can be infected by the mother, other family members, or hospital personnel. Enterovirus and respiratory virus outbreaks in hospital nurseries usually are associated with community outbreaks. Blood products are a potential source of nosocomial CMV infection, especially in premature infants born to CMV-seronegative mothers. These infections can be prevented by using only CMV-negative blood products or by filtering blood to remove leukocytes.

Viruses are the leading cause of illness in infants who come to medical attention with fever before 3 months of age.[31] Enteroviruses are particularly common in this age group. Data from the US National Enterovirus Surveillance System (NESS) covering the 1983–2003 period showed that 11% of all reported enterovirus infections occurred in neonates.[32] During summer and fall, enteroviruses account for most hospitalizations of young infants with suspected sepsis.[6,31] A study of hospitalized, febrile infants reported PCR detection of enterovirus in 28% of CSF samples collected during enterovirus season (i.e., June through October) compared with 11% detected during other months.[33] Enteroviruses and parechoviruses (previously echovirus 22 and 23) are common causes of sepsis-like illness, rash, and central nervous system infections in newborns.[34,35] Infections caused by adenovirus, rotavirus, norovirus, astrovirus, influenza, RSV, influenza, and others are common sporadic or seasonal causes of fever, systemic illness, gastrointestinal disease, and respiratory disease in newborns.[36–38]

Clinical Manifestations

Prematurity and Low Birth Weight.

Maternal viral infection can affect the outcome for the infant, even if fetal infection does not occur. Maternal herpangina has been associated with premature birth, low birth weight, and poor intrauterine growth.[39] Placental adenovirus infection has been associated with chorioamnionitis and preterm birth.[40] A study testing PCR on newborn dried blood spots to detect enterovirus RNA and herpesvirus DNA found an association between detection of CMV DNA and pregnancy-induced hypertension and preterm birth.[41] Adeno-associated virus-2, a member of the parvovirus family, has been associated with pre-eclampsia, stillbirth, and preterm birth.[42]

Increased risk of prematurity, low birth weight, and other unfavorable pregnancy outcomes has been ascribed to maternal dengue infection, but a review of 30 published studies concluded that evidence linking maternal infection to adverse pregnancy outcomes was inconclusive.[29] A virologic and serologic study of small-for-gestational-age neonates in Sweden did not find evidence of association with viral infection.[43] Infections that affect fetal growth or lead to premature birth usually produce other abnormalities suggesting congenital infection. A Dutch study of neonates with isolated intrauterine growth retardation concluded that screening small-for-gestational-age babies for congenital infection was not justified, with the possible exception of congenital CMV infection, which was found in 2% of cases.[44]

Spontaneous Abortion and Stillbirth.

Associations between spontaneous abortion or stillbirth and several viruses, including poliovirus, measles, rubella, mumps, influenza, parvovirus B19, HSV, CMV, and nonpolio enterovirus infection, have been reported.[45] The extent to which maternal HIV infection in the absence of immune deficiency increases the risk of fetal death or stillbirth is not clear.[45] Declining CD4 cell count and comorbidities are associated with increased risk of stillbirth, and in countries with high maternal seroprevalence, HIV can be an important cause of stillbirth.

Comparing estimates of the frequency of fetal deaths due to viral causes based on healthcare data with estimates from studies that used PCR for virus detection suggests that viral infections may play an important role in spontaneous abortion and fetal death. A study from northern England examined viral causes of fetal death (20–23 weeks) and stillbirths (≥24 weeks) over a 21-year period.[46] A viral cause was implicated in 0.5% (16 of 2953) of late fetal deaths and 0.6% (24 of 3954) of stillbirths. Studies that used molecular techniques for virus detection are summarized in Table 93.3. These studies suggest that viral infections may account for many cases of unexplained fetal death and stillbirth.[47–50]

TABLE 93.3

Viral Infections as Causes of Intrauterine Fetal Death and Stillbirth

Study	Method	Study Population	Results
Sweden, 2001	Placental and fetal tissue: PV B19 PCR, immunohistochemistry, histopathology	47 fetal deaths	15% PV B19
		37 miscarriages	5% PV B19
		29 induced abortions	0
		53 term, normal pregnancies	0
Germany, 2004	Prospective study of 1018 pregnancies with PV B19 infection	Infection before 20 weeks	11% fetal deaths
		Infection after 20 weeks	0 fetal deaths
Greece, 2008	Placental tissue: virus specific PCR	62 fetal deaths after 15 weeks	16% CMV; 13% PV B19; 5% HSV
		35 term, healthy newborns	3% CMV; 3% PV B19; 0 HSV
Australia, 2011	Liver, kidney, placenta: CMV PCR	130 stillbirths	15% CMV

CMV, cytomegalovirus; HSV, herpes simplex virus; PCR, polymerase chain reaction; PV, parvovirus.

Only a few studies have used modern laboratory methods to detect viral infection in spontaneous abortions, intrauterine fetal deaths, and stillbirths, and most focused on one or a few viruses and were performed in developed countries. It is likely that application of molecular methods in a wider variety of cultures and geographic areas will identify more viral causes and demonstrate that viruses are common causes fetal death and stillbirth.

Syndrome of Congenital Infection.

Hepatomegaly, splenomegaly, microcephaly, petechiae, jaundice, dermal manifestations of erythropoiesis, poor intrauterine growth, chorioretinitis, intracranial calcifications, deafness, thrombocytopenia, direct hyperbilirubinemia, or hepatitis in the neonate suggests prenatal infection. Other findings occasionally associated with congenital infection are cardiac defects, hydrocephalus, prematurity, and anemia. Clinical findings suggesting infection by a specific viral agent are listed in Table 93.4.

However, clinical findings alone are not diagnostic; laboratory evaluation is necessary to confirm the cause of congenital infection.

TABLE 93.4

Clinical Findings for Newborns Suggesting a Specific Congenital Viral Infection

Virus	Clinical Features
Cytomegalovirus	Microcephaly, hearing loss, petechiae, cholestatic jaundice
Rubella	Cataracts, heart disease, deafness
Varicella-zoster virus	Scarring of skin, limb hypoplasia, ocular abnormalities
Herpes simplex virus	Hydranencephaly, ocular disease, skin scars
Lymphocytic choriomeningitis virus	Microcephaly or macrocephaly, chorioretinitis
Zika virus	Microcephaly, retinal atrophy

Central Nervous System Infection.

Viral encephalitis or meningitis in the neonate can result from prenatal or postnatal infection. Abnormalities suggesting viral central nervous system disease often are subtle and nonspecific. They include lethargy, hypotonia, irritability, poor feeding, apnea, fever, and seizures. Prenatal viral infections can affect brain growth, leading to microcephaly. Although encephalopathy or encephalitis has been found in the neonate with many viral infections, CMV, enteroviruses, parechoviruses, and HSV are the most common known causes.

Sepsis Syndrome.

Clinical manifestations suggesting septicemia sometimes are associated with neonatal enterovirus, coxsackievirus, parechovirus, adenovirus, HSV, RSV, or influenza infections. Neonates with echovirus, parechovirus, or coxsackievirus infection can have pallor, lethargy, hypotension, apnea, acidosis, and respiratory impairment.[6] Rapid progression of disseminated HSV infection can produce shock, coagulopathy, fulminant hepatitis, and diffuse lung disease, often in the absence of vesicular skin lesions.[51] Postnatal CMV infection in very low birth weight premature newborns can cause a sepsis-like syndrome.[52,53] Neonatal infections due to RSV, adenovirus, and likely many other viruses sometimes manifest nonspecifically with apnea, lethargy, irritability, and poor feeding mimicking sepsis.[36,54]

Cardiac Insufficiency.

Viral infections produce congestive heart failure in the fetus or neonate by causing anemia or by directly damaging the myocardium. Fetal infection with human parvovirus B19 characteristically leads to profound anemia. Although many fetuses appear to recover in utero, hydrops fetalis and fetal death can result.[55] Rare cases of nonimmune hydrops fetalis also have been attributed to intrauterine CMV and adenovirus infection.[56,57] Viral myocarditis usually is caused by group B coxsackieviruses or echoviruses in the neonate, manifesting as cardiac failure or shock.[6]

Pulmonary Disease.

Lower respiratory tract disease is an unusual manifestation of congenital or perinatal viral infection, and when it occurs, usually is part of multisystem disease such as disseminated HSV or VZV infection. Postnatal lower respiratory infection or pneumonia in the neonate can be caused by any respiratory tract virus. Infection in newborns is associated with more severe lung disease than in older children, and systemic symptoms can mimic sepsis.

Ocular Abnormalities.

Table 93.5 lists ocular abnormalities found in patients with congenital and neonatal viral infections.[58–60] Abnormalities of the cornea and iris, chorioretinitis, vitritis, optic atrophy, and pigment retinopathy are associated most often with congenital infection. Chorioretinitis can be evident as scarring or as active lesions, sometimes accompanied by vitritis. In infants with microcephaly and possible congenital Zika virus infection, the most striking retinal abnormality is retinal atrophy, with evidence of uveitis and vasculitis notably absent.[5] Ocular abnormalities in newborns with congenital infection usually are associated with evidence of involvement of other organ systems, especially the central nervous system.

TABLE 93.5

Newborn Ocular Abnormalities Associated With Congenital and Neonatal Viral Infection

Ocular Abnormality	Viruses

Cataracts	Rubella, CMV, HSV, LCMV, VZV
Chorioretinitis	CMV, HSV, LCMV, VZV, Zika
Optic atrophy	HSV, VZV, rubella, CMV, LCMV, Zika
Microphthalmia	CMV, rubella, HSV, LCMV
Coloboma	CMV, rubella
Keratoconjunctivitis	HSV
Pigment retinopathy	Rubella
Glaucoma	Rubella
Iritis	HSV, rubella
Anophthalmia	CMV
Peter anomaly[a]	CMV
Horner syndrome[b]	VZV

[a] Central corneal or anterior chamber synechiae or cataract.

[b] Ptosis, meiosis, and ipsilateral absence of facial sweating.

CMV, cytomegalovirus; HSV, herpes simplex virus; LCMV, lymphocytic choriomeningitis virus; VZV, varicella-zoster virus.

Deafness.

Deafness commonly is associated with congenital infection caused by rubella virus and CMV. Newborns with diminished hearing of unknown origin should be evaluated for congenital infection. Congenital CMV infection accounts for approximately 15% to 20% of cases of bilateral, moderate to profound sensorineural hearing loss in the US children.[61] Because congenital CMV infection can cause progressive hearing loss, serial hearing evaluations throughout infancy and early childhood are recommended.

Approach to the Neonate With Suspected Viral Infection

Differential Diagnosis

Hepatomegaly, splenomegaly, petechiae, purpura, jaundice, microcephaly, encephalopathy, ocular abnormalities, anemia, thrombocytopenia, conjugated hyperbilirubinemia, or elevated serum hepatic transaminases should prompt the consideration of congenital viral infection. Nonspecific signs, such as fever, lethargy, anorexia, respiratory symptoms, and a sepsis-like syndrome, suggest possible perinatal viral, bacterial, or fungal infection. Congenital syphilis and toxoplasmosis can be indistinguishable clinically from congenital viral infection. Disseminated tuberculosis with central nervous system manifestations, hepatomegaly, and splenomegaly may initially suggest congenital viral infection.

Inborn errors of metabolism can cause encephalopathy, elevation of serum hepatic enzymes, thrombocytopenia, anemia, enlarged liver and spleen, jaundice, retinal pigment defects, and cataracts. Hypoglycemia, acidosis or alkalosis, hyperammonemia, crystalluria, urinary reducing substances, and a positive urine ferric chloride test result are clues to metabolic disease. Genetic abnormalities can produce central nervous system and other abnormalities similar to those seen with congenital infection.[62–64] Liver disease associated with neonatal giant cell hepatitis, biliary atresia, choledochal cyst, or intestinal obstruction can lead to hepatomegaly, splenomegaly, serum transaminase elevation, and cholestatic jaundice. Anemia, hyperbilirubinemia or hepatosplenomegaly due to rhesus or ABO isoimmunization, red blood cell biochemical defects, red blood cell structural defects, or immunologically mediated thrombocytopenia can be confused with congenital infection.

Fetal exposure to alcohol, anticonvulsants, or cocaine can impair brain growth, leading to microcephaly and neonatal encephalopathy similar to those observed in congenital infection. The prolonged use of intravenous vitamin E in premature infants has been associated with thrombocytopenia, encephalopathy, and cholestatic jaundice. Congenital leukemia and neuroblastoma can manifest as anemia, thrombocytopenia, and organomegaly.

Laboratory Diagnosis

Laboratory testing should focus on identification of virus by culture or molecular detection. The most likely causes should be selected on the basis of signs, laboratory abnormalities, and clinical context. The specimens required and the approach used for laboratory diagnosis depend on the specific virus considered, and they are discussed in those chapters.

Measurement of maternal or neonatal antibody responses is of limited value but can contribute useful information in certain circumstances. Negative immunoglobulin G (IgG) antibody results for specific agents indicate that maternal infection is absent or is very recent, virtually eliminating the likelihood of prenatal infection. The accuracy of IgM antibody testing of neonatal serum for viral diagnosis varies and depends on the virus, assay used, and laboratory. Results of test panels for IgG or IgM antibody to multiple possible causes of infection (i.e., TORCH titers) usually fail to establish an etiologic diagnosis or are not relevant, and they should not be used as the sole laboratory diagnostic assay.[65,66] Virus culture or PCR testing should be used to confirm IgM antibody test results.

Prevention and Treatment

Specific action to prevent or treat viral infection is required for newborns with or at risk for HSV, CMV, VZV, HIV, measles, influenza, and hepatitis B virus and is discussed in respective chapters. Antiviral treatment in the newborn is recommended for congenital CMV and perinatal HSV, HIV, VZV, and influenza virus infections. Management of infants with congenital or neonatal viral infection includes supportive care and anticipation of complications, such as hearing loss, cognitive impairment, seizures, cerebral palsy, impaired vision, and chronic liver disease.

Healthcare-Associated Infections in the Neonate

Laura Sass, M. Gary Karlowicz

As progressively smaller premature infants survive beyond the first few days of life, healthcare-associated infections (HAIs) have emerged as a major cause of morbidity and late mortality in the neonatal intensive care unit (NICU). Effective prevention and treatment of HAIs in the NICU require an understanding of the distribution of pathogens, the various patient-related risk factors for these infections, and the roles of medications and invasive procedures in predisposing to their occurrence.

Epidemiology and Anatomic Sites of Infection

Bloodstream infections (BSIs) are the most common HAIs in the NICU. They can occur in isolation or in association with urinary tract infections (UTIs)[1] and meningitis.[2] Endocarditis, osteomyelitis, pyogenic arthritis, ventilator associated pneumonia, peritonitis, conjunctivitis, and skin abscesses are important, less common HAIs (Table 94.1).

TABLE 94.1

Common Sites and Causes of Healthcare-Associated Infections in the Neonatal Intensive Care Unit

Site of Infection	Anticipated Causal Organisms					
	CoNS	*S. aureus*	Enterococci	GNR	*Candida*	Viruses
BSI	+++	++	++	++	+	−
CLABSI	+++	++	+	++	++	−
Osteomyelitis/septic arthritis	−	+++	−	+	+	−
Endocarditis	+	+++	+	+	+	−
Meningitis	+++	+	+	++	++	+
VAP	−	+	−	+++	+	+[a]
Peritonitis	+	−	+	+++	+	−
UTI	−	−	+	+++	++	−
Conjunctivitis	+	+	−	+	−	−
Skin or subcutaneous tissue	+	+++	−	+	+	+

[a] Includes respiratory syncytial virus, influenza virus, parainfluenza viruses, and enterovirus.

BSI, bloodstream infection; CLABSI, central line–associated bloodstream infection; CoNS, coagulase-negative staphylococci; GNR, gram-negative rods; *S. aureus, Staphylococcus aureus;* UTI, urinary tract infection; VAP, ventilator-associated pneumonia; +++, most common isolate; ++, frequently isolated; +, occasionally isolated; −, rarely or not isolated.

Late-Onset Sepsis

Late-onset sepsis is defined by the National Institute for Child Health and Human Development Neonatal Research Network (NICHD NRN) as BSIs occurring in neonates at or after 72 hours of age. Late-onset sepsis is most common in very low birth weight (VLBW) infants (<1500 g), for whom HAIs increase hospital length of stay by 19 days and cause 45% of deaths beyond 2 weeks of age.[3] Late-onset sepsis occurred in 21% of VLBW infants who survived beyond 3 days of age in the NICHD NRN study,[3] and similar rates have been reported from the Neonatal Networks in Canada (24%)[4] and Israel (30%).[5]

At the institutional level, the prevalence of late-onset sepsis in VLBW infants varies more: 11% to 32% in the NICUs of the NICHD NRN[3] and 7% to 74% in the NICUs participating in the Canadian Neonatal Network.[4] Data from the NICHD NRN confirm the risk of late-onset sepsis despite advances in medical care for the extremely premature infant, with 36% of infants born between 22 and 28 weeks' gestation having late-onset sepsis. The rate of late-onset sepsis is strongly and inversely associated with birth weight and gestational age, decreasing from about 60% among neonates with a gestational age of less than 25 weeks to 20% among infants born at 28 weeks' gestation.[6] Consequently, institutions caring for more extremely low birth weight (ELBW) infants have higher rates. Management practices, particularly those concerning the use and maintenance care of central venous catheters (CVCs) or peripherally inserted central catheters (PICCs), can further impact these rates of infection.[7]

Most cases of late-onset sepsis in neonates are associated with a central catheter (i.e., CVC or PICC)[3] and are referred to as central line–associated bloodstream infections (CLABSIs). The Centers for Disease Control and Prevention (CDC) and National Healthcare Safety Network (NHSN) definition[8] for a CLABSI includes isolation of a pathogen from one blood culture or of a skin commensal from two blood cultures, one or more clinical signs of infection (e.g., apnea, bradycardia, temperature instability) that are not related to an infection at another site, and presence of a CVC at the time the blood culture is obtained or within 48 hours before the development of the infection.

A rate of HAI that is linked to device use, such as for a CLABSI, helps control for variation in management practices from institution to institution. The preferred unit of measure is infections per 1000 catheter-days. The NHSN continues to recommend that CLABSI should be a major focus of surveillance and prevention efforts in NICUs and that institutions provide summary data on CLABSI rates for different birth weight groups. Values at the extremes of the NHSN data indicate problems with effective infection control or underreporting of CLABSI events, respectively. Individual NICUs are encouraged to monitor and compare their CLABSI rates with NHSN data, which are updated annually and usually published in December.[9]

In 2015, data on CLABSI rates from NHSN participating level III NICUs for the year 2013 showed a median number BSIs per 1000 catheter-days of 1 for infants weighing 750 g or less, 0 for those weighing 751 to 1000 g, and 0 for those weighing 1001 to 1500 g at birth.[9] The 90th percentile of BSIs per 1000 catheter-days was 6.3 for infants weighing 750 g or less, 4.4 for those weighing 751 to 1000 g, and 3.2 for those weighing 1001 to 1500 g at birth. These values represent a continuing decline in CLABSIs and device use. Data also were obtained for umbilical catheter–associated BSIs for the same period, which revealed low rates of infection in all weight categories.[9]

Coexistence of endocarditis, an infected intravascular thrombus, osteomyelitis, or pyogenic arthritis should be considered when BSIs persist in neonates. *Staphylococcus aureus* is the most common cause of endocarditis[10,11] and osteomyelitis[12,13] in neonates. These complications are uncommon, but the diagnosis should be considered when multiple blood cultures are positive in a neonate with a CVC.

Late-Onset Meningitis

Until recently, there were few surveillance data on the incidence of late-onset meningitis in the NICU. Consequently, considerable variation has existed in clinical practice concerning performance of a lumbar puncture in neonates with suspected late-onset sepsis. In a prospective study of 9641 VLBW infants who survived more than 3 days, late-onset meningitis occurred in 134 infants. This represented 1.4% of all infants and 5% of those who had a lumbar puncture performed. Compared with infants without septicemia, VLBW infants with meningitis were more likely to have seizures (25% vs. 2%), and were more likely to die (23% vs. 2%).[2] One third (45 of 134) of the infants with meningitis had blood cultures drawn simultaneously that were negative.

Because meningitis can alter duration of antibiotic therapy, affect long-term prognosis, and be complicated by parameningeal or brain abscess, all VLBW infants with suspected late-onset sepsis should have a lumbar puncture as part of the initial diagnostic evaluation, unless they are too critically ill to tolerate the procedure. In the latter case, lumbar puncture should be performed when clinical stabilization is achieved.

Urinary Tract Infection

UTI is a common HAI in adults and frequently is associated with an indwelling urinary catheter,[9] which seldom is used in VLBW infants. There is considerable variation in performing urine culture and analysis when late-onset sepsis is suspected.[14] Urine specimens obtained by bag collection from infants have notoriously high rates of contamination—up to 63%[15]—and are not recommended. Suprapubic bladder aspiration is performed less commonly because of the risk of serious, albeit rare, complications such as bowel perforation[16] and increased pain.[17] Sterile urethral catheterization can be performed easily by experienced nurses, even in ELBW infants, and has a potentially higher rate of success in obtaining urine compared with suprapubic bladder aspiration.[18,19]

Although prospective studies have not been performed, UTI, may be the second most common HAI in the NICU. The reported prevalence among premature infants ranges from 4% to 25%, but these reports are from the 1960s and do not represent the typical population in NICUs currently. A retrospective study reported an 8% rate of late-onset UTI among 762 VLBW infants in one NICU over an 11-year period.[20] UTI was more common in ELBW infants (12%) than in infants with birth weights between 1001 and 1500 g (6%). In a prospective study of one NICU over a 1-year period, the rate of HAIs was 17.5%, with only a 0.7% rate if UTIs.[21] When intervention-associated infections were examined, urinary catheter–associated UTIs (CAUTIs) accounted for up to 17.3%. The highest risk of HAIs was found for patients with a birth weight of less than 1000 g (relative risk, 11.8).[21]

Examining paired blood and urine cultures for 189 VLBW infants suspected of having late-onset sepsis, Tamim and colleagues detected UTI in 25%.[14] Among VLBW infants with UTIs, 62% (30 of 48) had a negative blood culture. Phillips and Karlowicz[1] reported a case series of 60 UTIs among NICU patients, primarily documented through specimens obtained by urethral catheterization when late-onset sepsis was suspected. Simultaneous BSIs with the same pathogen were detected in 52% of cases of *Candida* UTI and 8% of cases of bacterial UTI. Because most VLBW infants with UTI do not have a BSI, it is our practice to obtain urine for culture by sterile urethral catheterization or by suprapubic aspiration, when late-onset sepsis is suspected.

Ventilator-Associated Pneumonia

It is difficult to diagnosis healthcare-associated pneumonia in any patient population and particularly in the NICU population. New definitions from the CDC and NHSN in 2008 attempted to provide reproducible criteria for surveillance, classifying pneumonia as three specific types: clinically defined (PNU1), pneumonia with laboratory findings (PNU2), and pneumonia in immunocompromised patients (PNU3).[8] Infants and children usually fall into category PNU1. Diagnosis of ventilator-associated pneumonia (VAP) is especially difficult in neonates because noninfectious conditions such as respiratory distress syndrome and bronchopulmonary dysplasia are common and frequently cause radiologic abnormalities.

The NHSN has published specific guidelines adapted to infants younger than 1 year of age, but they are not specific to the premature infant. New benchmark data are becoming available through the NHSN. The highest incidence of VAP (i.e., 1.3 cases per 1000 ventilator days) occurs among infants with a median birth weight of less than 750 grams.[9]

A few investigators have attempted to establish reproducible criteria for VAP specific to the neonatal population. Cordero and coworkers[22] showed that finding purulent tracheal aspirate fluid with a positive tracheal culture in mechanically ventilated neonates in the absence of worsening clinical or radiologic findings is more consistent with clinically insignificant tracheal colonization than with VAP.

Apisarnthanarak and colleagues[23] performed a prospective cohort study addressing risk factors, microbiology, and outcomes of VAP in neonates. Their definition of VAP required new and persistent radiologic evidence of focal infiltrates more than 48 hours after initiating mechanical ventilation and treatment with antibiotics for more than 7 days for presumed VAP. By this definition, 19 (28%) of 67 of mechanically ventilated VLBW infants developed VAP, with a rate of 6.5 per 1000 ventilator-days.[23] Gram-negative bacteria were isolated from tracheal aspirates in 94% of VAP episodes, and most cases were polymicrobial. VAP developed in neonates at a median of ventilation day 30, and the risk of VAP increased by 11% for every additional week an infant was mechanically ventilated. VAP was strongly associated with mortality among neonates who required NICU care more than 30 days.[23]

Intestinal Perforation and Peritonitis

Peritonitis associated with intestinal perforation is a serious HAI in the NICU. Coates and associates[24] reported striking differences in the distribution of pathogens associated with peritonitis in 36 infants with focal intestinal perforation (FIP) compared with 80 infants with necrotizing enterocolitis (NEC). Enterobacteriaceae were found in 75% of NEC cases, compared with 25% of FIP cases. *Candida* species were found in 44% of FIP cases and in 15% of NEC cases. Coagulase-negative staphylococci (CoNS) were found in 50% of FIP cases and in 14% of NEC cases.

Peritoneal fluid cultures were positive and helped direct antimicrobial therapy in 40% (46 of 116) of cases.[24] Peritoneal fluid culture should be obtained for all neonates with intestinal perforation, regardless of cause.

Other Infections

Conjunctivitis is common in healthy term newborns. Few studies address its occurrence in the NICU. Diagnosis can be complicated because conjunctival colonization, especially with CoNS, is common in the NICU.[25] Occurrence rates of conjunctivitis in NICUs vary, with Haas and colleagues[26] reporting 5% in a prospective study and Couto and coworkers[27] reporting 12% (although infants of all birth weights were included). The most common pathogens are enteric gram-negative bacilli, but nonenteric flora such as *Pseudomonas aeruginosa* also can occur.[28]

Most neonatal skin infections are caused by *S. aureus*. Clinical manifestations include impetigo, cellulitis, soft tissue abscesses, and toxin-mediated diseases such as staphylococcal scalded skin and toxic shock syndromes.[29] Methicillin-resistant and methicillin-susceptible *S. aureus* (MRSA and MSSA) cause similar infections. Carey and associates reported an incidence of 4.8% for MSSA and 1.8% for MRSA among ELBW (<1000 g) infants' skin infections, with 53% of all NICU skin infections occurring in the ELBW cohort.[30] *P. aeruginosa* can cause ecthyma gangrenosum lesions even in a VLBW or ELBW infant.[31] Zygomycetes can cause progressive necrotizing skin lesions in neonates, with or without gastrointestinal manifestations.[32]

Pathogens of Late-Onset Infections

Gram-positive organisms are the predominant cause of late-onset sepsis in the NICU (48% to 70% of cases), but gram-negative organisms (19% to 25% of cases) and fungi (12% to 18% of cases) also are important.[3,33–36] Across many reports, the same pathogens cause most episodes: CoNS, *Candida* species, *S. aureus,* and Enterobacteriaceae (Table 94.2).

TABLE 94.2

Pathogens That Commonly Cause Late-Onset Sepsis in the Neonatal Intensive Care Unit

Pathogen	**Relative Frequency of Isolation**	**Comment**
CoNS	+++	Most common cause of CLABSI but decreasing with implementation of multipronged infection prevention
Staphylococcus aureus	++	Highest rate of focal complications; MRSA is a problem in some NICUs
Candida species	++	*Candida albicans* and C, *parapsilosis* are the most common species
Enteric GNR	++	Most common cause of fulminant sepsis; *Klebsiella* species is the most common GNR
Pseudomonas aeruginosa	+	GNR with highest case-fatality rate
Enterococcus species	+	Increased in importance as a nosocomial pathogen since the 1990s
Group B streptococci	+	Rate of late-onset cases unchanged, in contrast to dramatic decrease in early-onset cases with intrapartum antibiotics

CoNS, Coagulase-negative staphylococci; CLABSI, central line–associated bloodstream infection; GNR, gram-negative rods; MRSA, methicillin-resistant *Staphylococcus aureus*; NICU, neonatal intensive care unit; +++, most frequently isolated; ++, commonly isolated; +, occasionally isolated.

Very-late-onset sepsis (VLOS) is becoming more common as VLBW infants are living longer with ongoing needs for interventions. VLOS is defined as an infection after 120 days of life. The organisms that cause late-onset sepsis also cause VLOS.[34,37]

Usual Pathogens

The frequency of pathogens and likelihood that certain pathogens cause rapid progression to severe complications and death (i.e., fulminant sepsis) must be considered when choosing empiric therapy. Karlowicz and colleagues[33] reported that although gram-negative organisms caused only 25% of BSIs in their series, they caused 69% of *fulminant* late-onset BSIs. Of the gram-negative bacilli, *P. aeruginosa* caused 42% of fulminant cases and overall had a case-fatality rate of 56%, which contrasts with a case-fatality rate of less than 1% for CoNS.[33] Similar findings have been reported by others.[3,38]

CoNS are the most common pathogens causing late-onset sepsis, accounting for 35%[29] to 48%[3] of cases. Distinguishing between true BSI and pseudobacteremia can be difficult. The CDC and NHSN define a laboratory-confirmed bloodstream infection (LCBI) with common skin contaminant flora as ≥2 positive blood cultures drawn on separate occasions.[8] In the report of Stoll and coworkers[3] of late-onset sepsis, a rate of 48% for CoNS would have fallen to 29% if LCBSIs had been included, a rate similar to the 35% reported by Karlowicz and colleagues.[33] There has been a substantial decline in late-onset CoNS BSIs the past decade due to implementation of several infection prevention initiatives.[39]

Gram-positive organisms are the predominant pathogens in VLOS, although *S. aureus* and *Enterococcus* species can be more common than CoNS. Wynn and associates found that 48% of infections in VLBW infants were caused by gram-positive organisms, followed by gram-negative bacilli and then fungi. *Candida* species produced the highest organism-specific mortality rate in their cohort (33%), followed by gram-positive cocci (28%), but the highest organism-specific mortality rate (44%) was attributed to *S. aureus*, followed by *P. aeruginosa* (38%), similar to late-onset sepsis.[34]

Emerging Pathogens

The prevalence of pathogens in the community, healthcare, and NICU environments and the selective pressure of antibiotic use contribute to antibiotic-resistant infections in NICUs.[40] Gram-positive bacteria, including hospital- and community-associated MRSA (CA-MRSA)[30,41–45] and vancomycin-resistant *Enterococcus* *faecium,*[46] are serious problems in NICUs. The incidence of CA-MRSA varies widely across NICUs, and mortality rates for MRSA and MSSA infections remain high and frequently are not catheter related.[47] Gram-negative enteric organisms (e.g., extended-spectrum β-lactamase-carrying *E. coli* and *Klebsiella* spp.,[48–50] *AmpC* β-lactamase-carrying *Enterobacter* spp.,[51] metallo-β-lactamase–carrying enteric bacilli,[52] multidrug-resistant *Serratia marcescens,*[53,54] *Leclercia adecarboxylata*[55,56]), nonenteric organisms (e.g., *P. aeruginosa,*[57,58] *Burkholderia cepacia,*[59] *Chryseobacterium meningosepticum*[60]), and recently, highly resistant *Acinetobacter* spp. have emerged in NICU environments.[61,62]

In many instances, reservoirs containing the organism exist within the healthcare environment. Patients are exposed through the use of contaminated medical equipment or by the hands of caretakers, including family members. The former often results from breakdowns in the cleaning procedures used in the NICU or hospital environment,[44,52,54,63] and the latter results from ineffective use of hand hygiene.[57,64,65] Molecular fingerprinting of organisms has been useful for characterizing and controlling some outbreaks.[42,48,52,54,60] Control of NICU outbreaks of antibiotic-resistant organisms frequently requires vigorous application of infection control procedures (e.g., surveillance cultures, patient and staff cohorting, hand hygiene education interventions[66,67]) and active education about the factors that predispose to infection. The CDC began a 12-Step Campaign in 2002 to prevent antimicrobial resistance in various healthcare settings, and these valuable methods can be applied successfully to the NICU.[68]

Viral Infections

HAIs caused by viruses are uncommon in the NICU (incidence <1%),[69] but because of patient vulnerability and the propensity of viruses to spread patient to patient, the impact can be substantial. NICU outbreaks have been caused by respiratory syncytial virus (RSV),[70,71] influenza virus,[72] enteroviruses,[73,74] rotavirus,[75,76] adenovirus,[77] coronavirus,[78] parainfluenza,[79] and norovirus,[80,81] sometimes concurrently.[82] Attack rates can be as high as 33%.[72,74,77] Patients can be asymptomatic or have disease that is lethal,[76] and attributable costs can be high.[70] Viruses can be introduced into the

NICU by family members and by ill healthcare personnel (HCP).

RSV, adenovirus and parainfluenza infections manifest with cough, congestion, apnea, increasing oxygen requirement, or respiratory failure.[69,70] Parainfluenza and adenovirus infections manifest with epidemic conjunctivitis (in which ophthalmologic procedures can contribute to spread).[77] Coronavirus infection manifests with respiratory decompensation or abdominal distention and fever.[78] Infections with enteroviruses manifest with NEC-like signs, overwhelming septicemia, rash, or aseptic meningitis.[73] Rotavirus infection manifests with diarrhea that is frequent and watery in term infants, whereas in preterm infants, it more often is bloody and associated with abdominal distention and intestinal dilatation.[75]

Clinical Manifestations

The clinical features of sepsis in neonates are nonspecific. The most common clinical features are an increase in apnea or bradycardia (55%), gastrointestinal problems (46%) (i.e., feeding intolerance, abdominal distention, or bloody stools), need for respiratory support (29%), and lethargy or hypotonia (23%).[83] Predominant laboratory indicators are an abnormal white blood cell count (46%) (e.g., leukocytosis, increased immature white blood cells, or neutropenia), unexplained metabolic acidosis (11%), and hyperglycemia (10%). Unfortunately, the predictive values of these features are low; the best positive predictive value is for hypotension (31%).[83]

Abnormal heart rate characteristics (i.e., reduced variability and transient decelerations) occur early in the course of neonatal sepsis.[84] Although technology has been developed to calculate a heart rate characteristic index (HRCi),[85] Griffin and colleagues found that the HRCi performed similar to a clinical scoring system in predicting sepsis.[86]

The most common signs of CLABSI in neonates are fever (49%) and respiratory distress (30%).[87] Only 20% of patients had erythema or purulent discharge at the catheter insertion site.

Laboratory Diagnosis

The pretreatment diagnostic evaluation of suspected HAI should include at least two blood cultures (e.g., from any indwelling catheter along with peripheral sites), cerebrospinal fluid (CSF) culture, and urine culture. The isolation of CoNS from a single blood culture usually should be interpreted as a contaminant. A definitive diagnosis of a HAI due to bacterial or fungal species requires isolation of the organism from blood or another normally sterile body site or fluid. Exceptions are fungi such as *Aspergillus* and Zygomycetes, which can cause potentially fatal disseminated multiorgan infection but rarely are isolated from blood.[32,88] The use of serum biomarkers for fungal disease such as the 1,3-β-ᴅ-glucan assay in neonates requires more study.[89]

When viral infection is suspected, a presumptive diagnosis can be made by rapid diagnostic testing (e.g., positive direct fluorescent antibody [DFA] test for adenovirus, herpes simplex virus; enzyme immunoassay [EIA] for influenza, respiratory syncytial virus, or rotavirus; polymerase chain reaction tests) and a definitive diagnosis by isolation in viral culture. As they become available and validated for testing of body fluids such as blood, CSF, nasal washings, tracheal secretions, bronchoalveolar lavage fluid, or stool, they permit rapid viral diagnosis.

Attempts to identify dependable serum markers for diagnosis, severity, or prognosis have been somewhat successful, including use of the complete blood cell count,[90] C-reactive protein (CRP), various proinflammatory cytokines, serum hepcidin,[91] and procalcitonin (PCT) levels. Two meta-analysis of PCT showed potential for its use in the diagnosis of late-onset sepsis.[92,93] One study found PCT more accurate than the CRP level,[93] but studies have not had consistent results.[94]

Treatment

Empiric Therapy

Empiric antimicrobial therapy for suspected HAIs without a clinical focus in neonates should be guided by knowledge of the distribution, case-fatality rates of pathogens, and local susceptibility patterns of likely pathogens. An empiric antibiotic regimen should effectively treat gram-negative pathogens, particularly *P. aeruginosa* and other nonenteric flora. An aminoglycoside should be used for empiric treatment of possible gram-negative septicemia, the choice of which is determined by the antimicrobial susceptibility patterns of isolates from the NICU. Third-generation cephalosporins are not recommended for routine empiric therapy in neonates (unless knowledge of the patient's flora or the NICU pattern of infections specifically dictates) because: they do not have activity against most *P. aeruginosa* and some Enterobacteriaceae, routine use in NICUs has been associated with emergence of cephalosporin-resistant gram-negative bacilli,[95,96] and use has been associated with increased risk of candidemia in VLBW neonates.[97]

Ampicillin may be considered for empiric treatment of possible gram-positive septicemia, especially if *Enterococcus* and *Streptococcus agalactiae* are common pathogens causing late-onset sepsis in the NICU. If MRSA is prevalent in the community or NICU, vancomycin should be used as first-line therapy.[98] If MRSA is not identified, vancomycin should be discontinued promptly. If MSSA is identified, nafcillin is therapeutically superior to vancomycin.

Because CoNS sepsis is common, some physicians advocate broad empiric use of vancomycin.[99] This creates additional problems. Stoll and associates[3] found it alarming that 44% of all VLBW infants in the NICHD NRN were treated with vancomycin whether they had CoNS BSI or not. The Hospital Infection Control and Practices Advisory Committee of the CDC recommend avoiding empiric vancomycin therapy in patients with suspected sepsis to prevent the emergence and spread of vancomycin-resistant enterococci.[100] Karlowicz and coworkers[33] showed that avoidance of empiric use of vancomycin had no impact on the very low rate of fulminant CoNS sepsis and that the practice of beginning vancomycin only after CoNS was identified in blood culture did not prolong the duration of BSI.

Despite ongoing education, vancomycin continues to be the most commonly used drug in NICUs surveyed and was used inappropriately in 32% of instances.[68] In one study, application of guidelines for vancomycin use decreased neonatal vancomycin exposure from 5.2 to 3.1 per 1000 patient-days (40% reduction) and 10.8 to 5.5 per 1000 patient-days (49% reduction) in two NICUs with no change in causes of infection, duration of BSI, or incidence of complications or attributable deaths.[101] In a retrospective study of 4364 infants with CoNS BSIs across 348 NICUs, there was no 30-day survival benefit of empiric therapy with vancomycin versus therapy delayed 1 to 3 days after a first positive blood culture.[102]

In a retrospective review of 126 VLBW infants with CoNS sepsis (≥2 positive blood cultures), there was no difference in outcomes when infants were treated with vancomycin for 5 days after the last positive blood culture compared with a longer course (infants with endocarditis or infected thrombi were excluded).[103] This approach requires prospective study but is promising for reducing vancomycin use. Antibiotic stewardship specific to each NICU remains critical to the prevention of spread of resistant bacteria and avoidance of use of medications unnecessarily.

The use of empiric antifungal therapy for VLBW infants at high risk for candidemia is not standardized. Some studies suggest that empiric therapy may reduce mortality rates and improve outcomes for VLBW infants.[104] In a small, retrospective study, empiric antifungal treatment was given to critically ill neonates (<1500 g) with additional risk factors for invasive *Candida* infection who had received vancomycin or a third-generation cephalosporin, or both, for 7 days and had one or more of the following risks: receipt of total parenteral nutrition, mechanical ventilation, postnatal corticosteroid therapy, or an H_2-blocking agent or had a mucocutaneous *Candida* infection.[105] No *Candida*-related mortality occurred for patients who received empiric amphotericin B (0 of 6) compared with historical controls (11 of 18).[105] The decision to use an empiric antifungal agent for late-onset sepsis should be made on an individual basis.[106,107]

The suggested duration of therapy for HAIs by anatomic site is summarized in Table 94.3. The duration of treatment for individual patients should be determined by virulence of the pathogen, time it takes for follow-up cultures to become negative, rapidity of clinical response, time to negative blood culture, removal or retention of a CVC, and adequate drainage of any purulent foci.

TABLE 94.3

Suggested Duration of Therapy for Selected Healthcare Infections

Site or Manifestation of Infection	Duration of Therapy (Days)

BSI	10–14
Meningitis	14–21
CLABSI without removal of CVC	14[a]
Osteomyelitis or pyogenic arthritis	4–6 wk
VAP	10–14
UTI	10–14
Endocarditis	4–6 wk
Candidemia, catheter removed, rapidly resolving	10–14
Fungemia, disseminated	≈4 wk
Skin or subcutaneous lesion	7–10

[a] After first negative blood culture.

BSI, bloodstream infection; CLABSI, central line-associated bloodstream infection; CVC, central venous catheter; UTI, urinary tract infection; VAP, ventilator-associated pneumonia.

Adjunctive Therapy

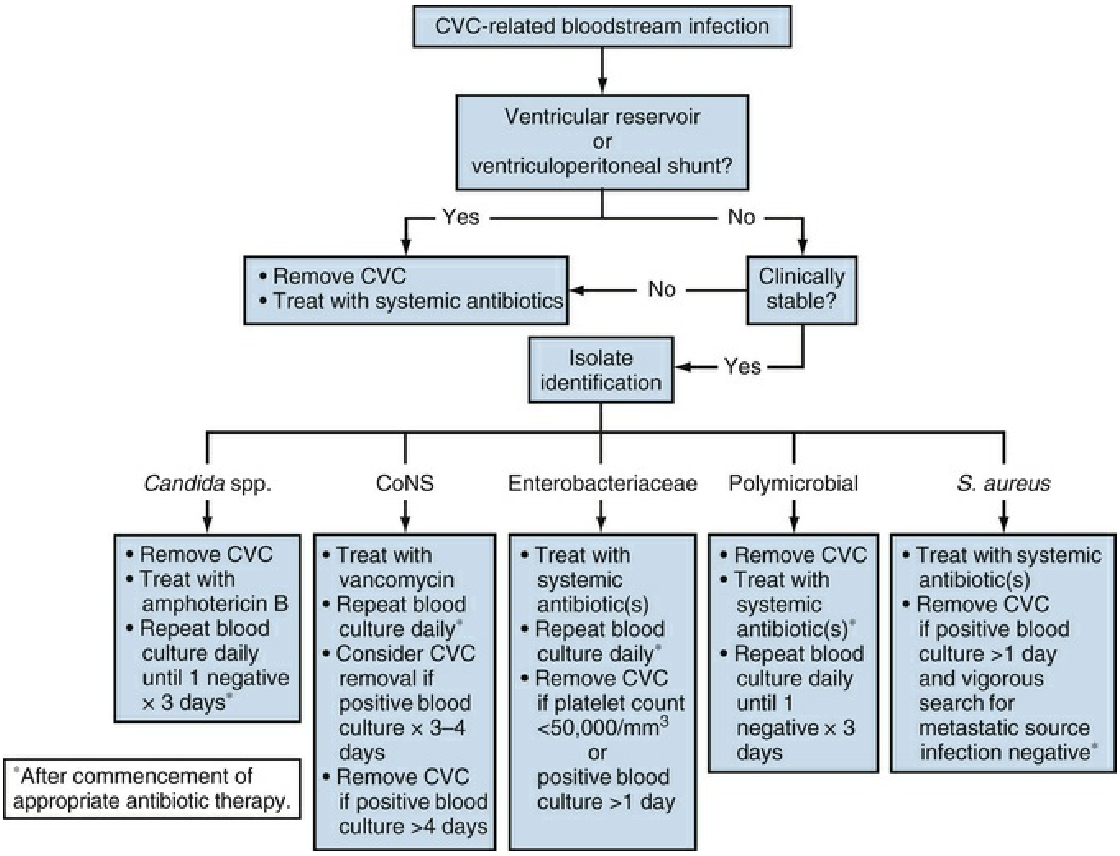
Several adjunctive therapies have been investigated for late-onset sepsis, including immune globulin intravenous (IGIV), hematopoietic growth factors (i.e., granulocyte colony-stimulating factor [G-CSF] and granulocyte-macrophage colony-stimulating factor [GM-CSF]), granulocyte transfusions, and pentoxifylline. IGIV,[108] G-CSF and GM-CSF administration[109] and granulocyte transfusions[110] have been evaluated in the Cochrane Database of Systematic Reviews, with the conclusion that there is insufficient evidence to support routine use in the treatment of neonates with sepsis. Pentoxifylline also has been reviewed in the Cochrane Database as an adjunct to antibiotics for treatment of suspected or confirmed sepsis or NEC, with results showing a decrease in all-cause mortality and decrease in length of stay, but the studies evaluated were small.[111,112] Larger clinical trials are needed to determine the usefulness of this adjunctive agent, but it may be promising.

A larger, multicenter trial used GM-CSF for prophylaxis of late-onset sepsis in neonates younger than 31 weeks' gestation and small for gestational age but did not show significant difference in sepsis-free survival.[113] A review of the data from studies of granulocyte transfusions in septic neonates demonstrated improved outcome in the situation of neutropenic depletion of the marrow storage pool, but associated morbidities included fluid overload, worsening hypoxia, respiratory distress from leukocyte sequestration in the lung, graft-versus-host disease, and risk of transmission of viral infections.[110] Careful assessment of the risks and benefits of leukocyte administration is required, as is the use of any of the other adjunctive therapy.[114]

Management of Central Line–Associated Bloodstream Infections

Removal of an intravascular catheter constitutes optimal management when a BSI occurs. Nevertheless, the vital importance of CVCs in critically ill neonates must be acknowledged, especially because successful treatment of CLABSI in situ has become more common.[115] BSIs can occur without being CLABSIs; differentiation of these two conditions can be difficult.

There have been no randomized trials to guide management of CLABSIs in the NICU, but several large, observational cohort studies have compared outcomes of late-onset sepsis in neonates with CVCs treated with or without CVC removal. Data suggest that management strategies depend on the pathogen and clinical condition of the infant. If treatment with the CVC in situ is attempted, antimicrobial agents should be administered through the contaminated catheter. The algorithm shown in Fig. 94.1 provides a framework for the management of CLABSIs in neonates until evidence becomes available from randomized trials.



CVC-related bloodstream infection
Ventricular reservoir or ventriculoperitoneal shunt?
Yes
No
• Remove CVC
• Treat with systemic antibiotics
No
Clinically stable?
Isolate identification
Yes
Candida spp.
CoNS
Enterobacteriaceae
Polymicrobial
S. aureus
• Remove CVC
• Treat with amphotericin B
• Repeat blood culture daily until 1 negative × 3 days*
• Treat with vancomycin
• Repeat blood culture daily*
• Consider CVC removal if positive blood culture × 3–4 days
• Remove CVC if positive blood culture >4 days
• Treat with systemic antibiotic(s)
• Repeat blood culture daily*
• Remove CVC if platelet count <50,000/mm3 or positive blood culture >1 day
• Remove CVC
• Treat with systemic antibiotic(s)*
• Repeat blood culture daily until 1 negative × 3 days
• Treat with systemic antibiotic(s)
• Remove CVC if positive blood culture >1 day and vigorous search for metastatic source infection negative*
*After commencement of appropriate antibiotic therapy.

FIGURE 94.1 Suggested management of central line–associated bloodstream infection (CLABSI) in neonates. CoNS, coagulase-negative staphylococci; CVC, central venous catheter.

Candida Species.

A single-center, retrospective study of 104 cases reported that failure to remove CVCs as soon as *Candida* sepsis was detected in neonates was associated with significantly increased mortality rates for *C. albicans* sepsis (i.e., case-fatality risk increase of 39%; number needed to harm of 2.6) and significantly prolonged duration of *Candida* sepsis regardless of the *Candida* species (i.e., median of 6 days vs. 3 days).[116] These findings were confirmed in a retrospective, multicenter study of ELBW infants with systemic candidiasis.[104]

The Infectious Diseases Society of America (IDSA) guidelines for treatment of catheter-related infections[115] and guidelines for management of candidiasis in NICU patients[117] strongly recommend that CVCs be removed as soon as *Candida* sepsis is detected (if feasible) and that a lumbar puncture and dilated retinal examination be performed.

Coagulase-Negative Staphylococci.

It has been difficult to interpret clinical studies of CoNS CLABSI in neonates because many studies required only a single positive blood culture for inclusion, including many cases of pseudobacteremia. In a series of 119 cases[118] of CoNS CLABSI with at least two positive blood cultures, investigators concluded that treatment in situ often could be successful, but they observed it was unclear how long clinicians should wait before abandoning sterilizing attempts and removing the CVC.

Karlowicz and colleagues reported that treatment in situ with vancomycin was successful in 46% of cases with CoNS CLABSI,[118] but none of 19 patients with CoNS BSI for more than 4 days after institution of antibiotic therapy had resolution until the CVC was removed. In contrast, 79% of cases with CoNS BSI for 2 days or less were successfully treated without CVC removal; the successful treatment rate decreased to 44% when BSI persisted for 3 to 4 days.[118] When CoNS CLABSI persists in neonates whose catheter is vital to clinical care, it is our practice to administer antibiotic treatment through the CVC for 2 days and perhaps as long as 3 to 4 days in special circumstances but never beyond 4 days of persistent bacteremia before removing a CVC.

Although the use of antibiotic lock therapy for 10 to 14 days in combination with systemic antibiotic treatment for the treatment of CoNS CLABSI is part of the 2009 IDSA treatment guidelines for short- and long-term CVC,[115] the role of a vancomycin lock for therapy or prevention in the NICU requires further study.[119]

Enterobacteriaceae.

Although Enterobacteriaceae are a common cause of late-onset sepsis, data are limited concerning CLABSI. In a report of 53 cases of Enterobacteriaceae CLABSI in neonates, resolution of infection was reported in 45% of cases with the use of gentamicin or tobramycin without CVC removal.[120] Successful treatment of Enterobacteriaceae with a BSI of more than 1 day's duration was uncommon without removal of the CVC.

Attempting to treat Enterobacteriaceae BSI with CVC in situ was not associated with an observable increase in mortality, morbidity, or recurrence. Severe thrombocytopenia (platelet count <50,000/mm^3) on the first day of Enterobacteriaceae BSI did not resolve until the CVC was removed in 82% of cases.[120] It is our practice to remove the CVC in cases associated with severe thrombocytopenia or if Enterobacteriaceae BSI persists for more than 1 day after commencing appropriate antibiotic treatment.

Staphylococcus aureus.

For adults, removal of the CVC is advised in cases of *S. aureus* BSI, unless there is a compelling reason to conserve the catheter.[115] There are few published reports concerning *S. aureus* CLABSI in neonates or children. In a review of 154 cases of *S. aureus* CLABSI in 112 patients in one institution (including 12 premature neonates),[14] patients had complications related to infection (excluding prolonged bacteremia), with recurrence being most common. The rate of complications was lower among the patients whose catheter was removed less than 4 days after onset of infection compared with those whose catheter was not removed or was removed more than 4 days after onset.[121]

Data on treating *S. aureus* CLABSI in situ are conflicting, with some showing poor success.[122] Most cases that were treated successfully with a CVC in situ showed resolution of MSSA BSI within 24 hours of starting a penicillinase-resistant penicillin. Focal complications (e.g., soft tissue abscesses, endocarditis, osteomyelitis) may be more important risk factors for persistent *S. aureus* BSI than retention of the CVC. It is our practice to use a cautious approach, removing the CVC immediately if infection persists more than 1 day after initiation of appropriate antibiotic treatment, especially if no other source of *S. aureus* infection is identified.

Polymicrobial Infections.

Polymicrobial BSI in neonates accounts for about 10% of cases of late-onset sepsis.[123] It usually occurs later than monomicrobial sepsis in neonates with a severe underlying condition and among those with longer-indwelling CVCs.

CoNS is the most common organism recovered from culture, and it is seen in combination with other gram-positive and gram-negative organisms.[123] It is prudent to remove CVCs as soon as possible in cases of polymicrobial sepsis.

Management of Persistent Bloodstream Infections

The likelihood of adverse outcomes, such as focal complications, increases when BSI persists in neonates. Although it is uncertain whether focal complications are the cause or the consequence of persistent BSI, it is imperative that clinicians obtain serial blood cultures to document resolution of BSI and perform thorough diagnostic evaluations searching for focal complications if BSI persists. When BSI persists, clinicians must make management decisions concerning the timing of CVC removal and changes in antimicrobial therapy. Several cases have been reported of successful treatment of persistent CoNS CLABSIs with CVCs in situ without adverse consequences by adding rifampin to standard antistaphylococcal antimicrobial therapy.[124,125]

Some pathogens, especially *Candida* species, may continue to be isolated from blood cultures despite prompt removal of the CVC and administration of antifungal therapy. In one series of 96 neonatal cases, candidiasis lasted more than 7 days in 30% of cases.[126] The risk of focal complications of invasive candidiasis was significantly increased in cases with persistent compared with nonpersistent BSI (48% vs. 13%). The most common focal complications were "fungus ball" uropathy (29%), renal infiltration (20%), abscess (19%), and endocarditis (9%).[126]

Because more than one half of neonates with persistent candidiasis do not have focal complications, Chapman and Faix[126] suggested that aggressive imaging for focal complications be reserved for cases in which blood cultures remain positive despite several days of antifungal therapy or if there are clinical signs suggesting focal complications. Noyola and associates[127] documented focal complications in 23% of 86 neonates with candidemia, including some with only one positive blood culture, and the investigators recommended renal, cardiac, and ophthalmologic diagnostic evaluations for all neonates with candidemia because the existence of focal complications may affect the duration of therapy and outcome.

The prevalence of persistent BSI was 22% in a series of 335 cases of bacteremia in one NICU.[128] In this case series, the frequent decision to treat bacterial BSI with a CVC in situ contributed to the high prevalence of persistent cases. The prevalence of focal suppurative complications (i.e., osteomyelitis, septic arthritis, abscess, infected thrombus, or endocarditis) was significantly increased with the duration of BSI and was greater with persistent non-CoNS BSI compared with persistent CoNS BSI (28% vs. 3%).[128] *S. aureus* caused 50% of persistent non-CoNS BSIs and 67% of the cases with focal complications.

The study authors recommended that all neonates with persistent BSI undergo extensive evaluation for focal complications, especially for endocarditis, osteomyelitis, and soft tissue abscesses.[128] This evaluation is especially important in cases of persistent BSI caused by *S. aureus* or Enterobacteriaceae because the bacteremia does not resolve until the soft tissue abscesses (sometimes suppurative phlebitis) or bone or joint infections are drained or until the intravascular clot dissolves.

Prevention of Healthcare-Associated Infections

Risk factors for CLABSI have been extensively examined and include the use of total parenteral nutrition,[3] mechanical ventilation,[3] previous BSIs,[105] and previous exposure to third-generation cephalosporins.[96] A cohort study of monozygotic and dizygotic premature infants concluded that 49% of variance in the occurrence of late-onset sepsis might result from genetic factors and 51% from environmental factors.[129]

Manipulation of the central line increases the risk of CLABSI, including placement of the lines, maintenance of the dressing, and repeated entry into the CVC system. Approaches that minimize these interventions decrease the rate of CLABSI. Successful programs address technical and contextual factors, often with the use of care bundles and guidelines.[130] Bizzarro and coworkers performed a quality improvement initiative designed to reduce their NICU infection rate by implementing several interventions using a multidisciplinary approach and using guidelines for CVC care.[7] Interventions were associated with a decrease in the rates of CLABSI from 8.40 to 1.28 cases per 1000 central line–days and late-onset sepsis from 5.84 to 1.42 cases per 1000 patient-days.[7]

Hand decontamination by HCP is the most effective means of preventing HAIs,[131] but it often is overlooked or performed poorly in the NICU environment.[67,132] Activities such as skin contact, respiratory care, and diaper changes are independently associated with increased hand contamination.[131] The CDC recommends that HCP use alcohol-based hand rubs rather than antimicrobial soaps.[131] Alcohol-based hand rubs have excellent antimicrobial spectrum against bacteria, fungi, and viruses. The alcohol-based hand rubs also have a rapid speed of action and are the least likely to cause hand dermatitis in HCP.[131] The institution of a hand hygiene taskforce that includes problem-based and task-oriented education programs can help with hand hygiene compliance and a concurrent decrease in the infection rate. It is important to have continuous staff involvement to ensure success.[67,133]

The use of chlorhexidine gluconate (CHG) in the NICU for CVC care is increasing, with one survey showing 62% of respondents using CHG as off-label use because it is not approved by the US Food and Drug Administration for use in children younger than 2 months of age.[134] There are no data to support the use of CHG for patient bathing in the neonatal or pediatric population.

CHG antisepsis has been part of the Central Venous Catheter Guidelines in the United Kingdom since 2007,[135] but evidence from clinical trials has been lacking. In 2009, Soothill and colleagues at Great Ormond Street Hospital (GOSH) for Children reported a “profound, sustained fall” in CLABSIs from 12 to 3 per 1000 line-days in their hematopoietic stem cell transplantation pediatric patients.[136] This profound, sustained fall in CLABSIs occurred after changing from 30-second CVC hub antisepsis with 70% isopropyl alcohol to a 30-second CVC hub antisepsis with 2% CHG. Because the 30-second hub scrub was identical in the CHG and the 70% isopropyl alcohol groups, the significant reduction in the CLABSI rate was more likely associated with the introduction of CHG CVC hub antisepsis and not the friction of the 30-second hub scrub.

Soothill and colleagues[136] also reported that CVC hub antisepsis with 2% CHG was associated with a “marked fall” in the CLABSI rate throughout GOSH. The advantage of 3.15% CHG CVC hub antisepsis over 2% CHG CVC hub antisepsis, as used by Soothill and colleagues at GOSH,[136] is that 3.15 % CHG has similar effectiveness but requires only one half of the time. The 3.15% CHG CVC hub antisepsis takes 30 seconds (i.e., 15-second hub scrub followed by a 15-second drying time) compared with 60 seconds for the 2% CHG CVC hub antisepsis (i.e., 30-second hub scrub followed by a 30-second drying time), as described in the 3.15% and 2% CHG package inserts.

Premature infants require respiratory and enteral support. Systemic corticosteroid and H_2-blocking agents have been used to prevent chronic lung disease and enhance gastrointestinal function, respectively. Dexamethasone therapy for VLBW infants is associated with increased risk of late-onset sepsis.[104] Use of H_2-blocking agents in VLBW infants is associated with higher rates of NEC,[137] BSIs,[104] and candidemia.[104,138] Avoiding the use of dexamethasone and H_2-blocking agents should reduce rates of late-onset sepsis.[139]

Human milk contains several substances that provide a beneficial effect to the premature infant, including enhancement of innate immunity and enhancement of mucosal barriers. Establishing full enteral feedings with human milk is associated with lower risks of late-onset sepsis in ELBW infants.[140] Human milk was found to reduce the development of NEC by sixfold in a study of 202 VLBW infants who received more than 50% compared with those who received less than 50% human milk in the first 14 days of life.[141]

The use of bovine lactoferrin (bLF) also is being studied for the prevention of sepsis. The Italian Study Group for Neonatal Infections studied the effect of lactoferrin with or without probiotics (*Lactobacillus* GG) and found a decrease in the rate of infection in infants who were given bLF (6%) compared with the placebo group (18%).[142] The use of oral lactoferrin was reviewed in a 2015 Cochrane Database, which concluded that evidence of low to moderate quality suggests that oral lactoferrin prophylaxis decreases late-onset sepsis in preterm infants. Completion of several ongoing trials may improve the quality of the evidence.[143]

The American Academy of Pediatrics Red Book 2015 Committee on Infectious Diseases said that the use of fluconazole prophylaxis to prevent invasive candidiasis in ELBW infants should be considered in nurseries with moderate (5%–10%) to high (>10%) rates of invasive candidiasis after infection control practices are optimized.[144] Kaufman and colleagues demonstrated a significant reduction in invasive fungal disease in 100 ELBW infants given fluconazole prophylaxis or placebo (0% vs. 20%, respectively), but the level of invasive candidiasis was higher in their NICU than in centers in the NICHD NRN at that time.[145]

The strongest effect appears to occur when prophylaxis is targeted to high-risk patients with birth weights of less than 1000 g and with use of CVCs. It may be reasonable to use fluconazole with dosing of 3 mg/kg twice per week until intravenous (central or peripheral) access is no longer needed in the high-risk populations, starting in the first 2 days of life.[139] Nystatin prophylaxis also has been studied, although not as extensively, and it shows potential effectiveness in the same high-risk population but may have increased gastrointestinal side effects compared with fluconazole.[139]

The use of probiotics in the NICU is controversial because probiotics used in studies have varied and not all probiotics can be considered the same. Different strains of probiotic may have common characteristics and action but also may have unique properties and actions toward specific targets; generalization is difficult.[146] A meta-analysis of 15 randomized, controlled trials of enteral probiotic supplementation recommended the use of probiotics in preterm infants if a suitable product is available because the benefits of the reduction of death and NEC disease were clear to the inestigators.[147]

One multicenter, randomized, controlled trial showed a higher prevalence of sepsis and periventricular leukomalacia among infants weighing 500 to750 g in the probiotic group.[148] Another randomized, controlled trial showed an increased association of vancomycin-resistant enterococcus colonization in VLBW infants given probiotics.[149] Despite some studies showing benefit, evidence of infection prevention and product safety require further elucidation before a universal recommendation of probiotic supplementation, especially with regard to the strains used.

Infections in Solid Organ Transplant Recipients

Michael Green, Marian G. Michaels

Solid-organ transplantation (SOT) is an accepted therapy for end-stage disease of many organs. Survival after transplantation has increased substantially, and the expanding numbers of immunosuppressed children are at risk for infection after transplantation.

Predisposing Factors

Factors predisposing to infection after SOT can be divided into those that exist before transplantation and those due to intraoperative and posttransplantation events (Box 95.1).

Box 95.1

Predisposing Factors for Infections After Organ Transplantation in Children

Pretransplantation Factors

Underlying diseases, malnutrition

Specific organ to be transplanted

Age of patient

Previous exposures to infectious agents

Previous immunizations

Intraoperative Factors

Duration of transplantation surgery

Exposure to blood products

Technical problems

Organisms transmitted in donor tissue

Posttransplantation Factors

Immunosuppression

- Immediate posttransplant immunosuppression
- Maintenance immunosuppression
- Augmented therapy for rejection episodes

Indwelling cannulas

Nosocomial exposures

Community exposures

Pretransplantation Factors

The specific organ that is transplanted is the most important determinant of the location of infection, especially during the first 3 postoperative months.[1] The chest, abdomen, and urinary tract are the most common sites of infection after thoracic, liver, and kidney transplantation, respectively. Explanations for these site-specific infections include local ischemic injury, bleeding, and potential intraoperative contamination.[2]

The underlying condition causing organ failure also can increase the risk of infection after SOT. For example, cystic fibrosis (CF) predisposes to pseudomonal and fungal infections after lung transplantation. Palliative surgery, such as for cardiac, biliary, and urologic conditions, increases the technical difficulty of the transplantation procedure, enhancing the risk of subsequent infection.[3] The severity of disease at the time of transplantation correlates with the risk of postoperative morbidity and mortality.[4] Longstanding malnutrition predisposes children to infection; attempts to correct nutritional deficits with parenteral alimentation carry attendant risks of catheter-associated infection. Mechanical ventilation while awaiting transplantation increases the risk of colonization and infection with nosocomial pathogens, many of which have multidrug resistance.

Age is an important determinant of susceptibility to and severity of infection after transplantation. Young compared with older children undergoing transplantation can experience greater disease severity due to respiratory viruses. Primary infection with cytomegalovirus (CMV) or Epstein-Barr virus (EBV) is associated with worse outcomes compared with reactivation infections.[5,6] In contrast, infections with other pathogens (e.g., *Cryptococcus* species) rarely occur before young adulthood. Younger age at the time of transplantation also is associated with an increased rate of infection during the first few years after transplantation.[7] Young children who are not immunized fully before transplantation remain susceptible to vaccine-preventable infections, and those immunized after transplantation may respond suboptimally due to immunosuppression.[8]

Transplant recipients can acquire pathogens from their donors who have active or latent infections at the time of organ harvesting. Examples include CMV,[9–11] EBV, *Toxoplasma gondii, Histoplasma* spp., West Nile virus (WNV), hepatitis B (HBV) and C viruses (HCV), and human immunodeficiency virus (HIV).[12] Screening to exclude donors with HIV or active HBV infection is standard practice, whereas organs from HCV-positive donors sometimes are used in HCV-positive recipients. Similarly, organs from HBV core antibody–positive donors sometimes are used in individual cases. Bacteria or fungi colonizing the donor's respiratory tract can cause disease after lung transplantation.[13] Unrecognized bacteremia or viremia in the donor also creates a risk for any recipient.

Intraoperative Factors

Operative factors unique to each SOT procedure can affect the risk of infection. For example, the type of biliary reconstruction used in liver transplantation influences the risk of infectious complications.[14] Surgical events during the operation also alter the risk of infection. Injury to the phrenic, vagal, or recurrent laryngeal nerves affect pulmonary toilet, predisposing a lung transplant recipient to pneumonia. Additional factors, including ischemia, prolonged operative time, contamination of the operative field, and bleeding at or near surgical sites, increase the risk of postoperative infections.

Posttransplantation Factors

Immunosuppression is the major risk for infection after transplantation. Although immunosuppressive regimens evolve to achieve more specific control of rejection with less impairment of immune function, all regimens interfere with host defenses. Treatment of rejection exacerbates this risk, as does use of antilymphocyte preparations or other biologic agents[11,14,15] (see Chapter 108). As newer immunosuppressive agents are introduced, clinicians must be alert for known and unknown infectious risks and manifestations.[16]

Technical problems after transplantation are major risk factors for infectious complications. Thrombosis of the hepatic artery predisposes to hepatic abscesses and bloodstream infections (BSIs) after liver transplantation.[17] Vesicoureteral reflux predisposes to graft pyelonephritis in renal transplant recipients.[15,18] Mediastinal bleeding requiring re-exploration predisposes to mediastinitis and BSI in thoracic organ transplant recipients.[19]

Indwelling cannulas and nosocomial exposures are a significant risk for infection. Central venous catheters (CVCs) are a risk factor for BSI. Urethral catheters predispose to urinary tract infection (UTI), and prolonged endotracheal intubation is associated with pneumonia. All transplant recipients are at risk for transfusion-associated pathogens. Children undergoing transplantation during the winter often are exposed nosocomially to common respiratory viruses. Areas of the hospital with heavy contamination with pathogenic fungi (e.g., *Aspergillus* species) increase the risk of invasive fungal disease. Nosocomial transmission of multidrug-resistant bacteria predisposes to infection with these pathogens.

Timing of Infections

The timing of specific infections usually is predictable, regardless of the type of organ transplanted. Most clinically important infections occur within the first 180 days and tend to manifest at stereotypical times after transplantation. However, the timing of certain pathogens (e.g., CMV) can be affected by the use of prophylactic strategies, augmentation in immune suppression, or the need for additional surgery.

In evaluating possible infection, it is useful to divide risk periods after transplantation into three major intervals: early (0–30 days after transplantation), intermediate (30–180 days), and late (>180 days). Some infections can occur throughout the posttransplantation course. Although exceptions occur, these divisions provide a useful framework for the approach to and differential diagnosis of a patient with fever after transplantation (Table 95.1).

TABLE 95.1

Timing of Infectious Complications After Transplantation[a]

Early Period (0–1 mo)	Middle Period (1–6 mo)	Late Period (≥6 mo)
BACTERIAL INFECTIONS	**VIRAL INFECTIONS**	**VIRAL INFECTIONS**
Gram-negative enteric bacilli Small bowel, liver, neonatal heart *Pseudomonas* and *Burkholderia* spp. Cystic fibrosis: lung Gram-positive organisms All transplant types **FUNGAL INFECTIONS** All transplant types	Cytomegalovirus All transplant types Seronegative recipient of seropositive donor Epstein-Barr virus All transplant types Seronegative recipient Small bowel highest risk group Varicella-zoster virus All transplant types **OPPORTUNISTIC INFECTIONS** *Pneumocystis jirovecii* All transplant types	Epstein-Barr virus All transplant types, but less than middle period Varicella-zoster virus All transplant types Community-acquired viral infections All transplant types **BACTERIAL INFECTIONS** *Pseudomonas* and *Burkholderia* spp. Cystic fibrosis: lung Lung recipients with chronic

[a] Listed in decreasing order of relative importance.

Early Infections.

Early infections (0–30 days after transplantation) usually are associated with pre-existing conditions or surgical complications. Bacteria or yeast are the most frequent pathogens; 50% or more of all bacterial infections after transplantation occur during the early posttransplantation period.[19,20] Superficial or deep surgical wound infections predominate.

Technical difficulties, particularly those resulting in anastomotic leaks or stenoses, are important risk factors after most types of SOT. Donor-derived infections also can manifest. They most frequently are bacterial infections such as bacteremia (relevant to all SOT recipients), subclinical bacterial infection of the airway in lung transplant recipients, or urinary tract infection in renal transplant recipients.[12] Acute donor viral infections, such as West Nile virus or adenovirus, also can manifest in recipient.

Intermediate Period Infections.

The intermediate period (31–180 days after transplantation) is the typical time for manifestation of infection due to latent organisms transmitted from donor organs or blood products and for reactivation of latent infections in the recipient. This period also is the time when classic opportunistic infections are seen. In the absence of antiviral prophylaxis, CMV infection peaks,[9–11] and EBV-associated posttransplantation lymphoproliferative disorders (PTLDs),[6,21,22] *Pneumocystis jirovecii* pneumonia (PCP),[23–25] and toxoplasmosis[26] typically manifest.

Late Infections.

Published data on late infectious complications (>180 days after transplantation) are limited. Rates and severity of infection in children 6 months or more after transplantation are similar to those observed for otherwise healthy children[7] because most pediatric transplant recipients are by then maintained on low levels of immunosuppressing drugs. However, chronic or recurrent infections occur in a subset of transplant recipients who have uncorrected anatomic or functional abnormalities (e.g., vesicoureteral reflux, biliary stricture).

Children experiencing chronic lung rejection that manifests as bronchiolitis obliterans syndrome (BOS) frequently become infected with *Pseudomonas, Stenotrophomonas,* and *Aspergillus* species.[13,27] Infections due to varicella-zoster virus (VZV)[28] and CMV, particularly in children who receive prolonged prophylaxis,[29] and EBV-associated PTLDs can manifest in the late period.[30]

Infections Occurring Throughout the Postoperative and Posttransplantation Course.

Central venous catheters, percutaneous indwelling catheters, and nasotracheal or endotracheal tubes pose a risk of infection for the entire time of cannulation. The risk of community-acquired respiratory viruses is seasonal. Diagnostic studies should be modified according to these considerations.

Bacterial and Fungal Infection

Except for infections related to the use of indwelling catheters, bacterial infections tend to occur at sites near the transplanted organ. Recovery of bacteria with multidrug resistance is common. Knowledge of prior culture results and local antimicrobial resistance patterns help guide empiric antibiotic use.

Renal Transplantation.

Septicemia originating from the urinary tract, the lower respiratory tract, or the operative wound accounts for most life-threatening infections early after renal transplantation.[18,31] UTI, especially pyelonephritis, is the most common infectious complication, accounting for up to 50% of episodes.[32,33] Gram-negative organisms predominate.[31–33] One third of pediatric renal transplant recipients experience recurrent UTIs.[34] The incidence may be decreased with the use of ureteroneocystostomy and daily prophylactic use of trimethoprim-sulfamethoxazole (TMP-SMX).[19,35]

Infection of the lower respiratory tract occurs in 10% to 25% of adult recipients and can occur more than 1 year after transplantation.[31,34] Episodes of pneumonia caused by gram-negative and gram-positive bacteria can be severe.[36]

Fungal infections are uncommon. *Candida* spp. predominate, and the urinary tract is the most common site.[18] However, patients also are at risk for infection with opportunistic fungi such as *Aspergillus* spp.[34,37] Those with fungal infections appear to be at higher risk for graft loss.[38]

Liver Transplantation.

Bacterial and fungal infections are common early.[39–42] Intra-abdominal infection or a CVC predispose to BSIs, but these infections can occur without an obvious source. Enteric gram-negative organisms account for more than 50% of episodes. Bacterial infections involving the abdomen or surgical wound are common. Infectious complications in the transplanted liver also occur. Historically, the most important complication was hepatic abscess, which was associated with hepatic artery or portal vein thrombosis. However, the introduction of frequent Doppler surveillance studies to assess for thrombosis, coupled with the use of operative thrombectomy and thrombolysis, has marked reduced the frequency of hepatic abscesses.

Ascending cholangitis is common after liver transplantation, and it usually is associated with biliary tract abnormalities. The diagnosis is made on clinical grounds for a patient with fever and biochemical evidence of biliary tract inflammation (see Chapter 64). Enteric gram-negative bacilli and enterococcal species predominate. However, cholangitis and acute graft rejection can mimic one another, and a liver biopsy should be performed to differentiate these processes. Cholangiography is performed to assess the status of the biliary tract for patients with proven cholangitis.

As many as 40% of children develop a fungal infection during the first year after liver transplantation.[41] *Candida* spp. predominate, and infection usually is associated with an intra-abdominal focus or CVC. Data suggest the rate of invasive candidiasis is only 2.5%.[43] Episodes of invasive aspergillosis are uncommon but can be fatal.[44]

Children undergoing liver transplantation for CF are at increased risk for *Aspergillus* infection.[41]

Intestinal Transplantation.

As increasing numbers of children undergo intestinal transplantation, many have combined procedures with transplantation of liver or multiviscera. Bacterial infection (most commonly with BSI) occurs frequently,[20,44–46] at a rate of approximately 1.4 episodes per pediatric intestinal transplant recipient.[47] Disruption of the mucosal barrier associated with harvest injury or rejection commonly leads to BSI.[45,46] Coagulase-negative staphylococci, enterococci, gram-negative bacilli, and *Candida* spp. account for most episodes.

Although most episodes of BSI occur in the first 3 to 6 months after transplantation, later episodes also occur. Intra-abdominal and wound infections occur in more than one third of patients, typically soon after transplantation.

Heart Transplantation.

Death from infection after pediatric heart transplantation has decreased in recent years. Infection now accounts for less than 15% of deaths in the first year and between 5% and 10% of later deaths.[48] Infection of the lower respiratory tract (including pneumonia and lung abscess) is the most common infection after pediatric heart transplantation.[9,49–52] Mediastinitis also is an important infection, particularly if re-exploration of the chest is required. Pathogens associated with mediastinitis include *Staphylococcus aureus* and gram-negative bacilli. Young children are at increased risk for invasive infection due to *Streptococcus pneumoniae*.[52,53] Infants represent a unique population and have an increased risk of serious bacterial and fungal disease.[52,54,55]

Fungal infections, although uncommon, can be severe after heart transplantation. *Candida* spp. predominate, but serious *Aspergillus* infection also occur.[49]

Lung and Heart–Lung Transplantation.

Infection is the major cause of death in the first year after pediatric lung transplantation.[56] Infection was the primary or contributing cause of death for most patients who died after the perioperative period in one series,[27] and it was second only to graft failure in the 2013 International Registry data.[56] Infection is the third major cause of death, following bronchiolitis obliterans syndrome and primary graft failure, for children who die more than 1 year after transplantation.[56] Recipients are at high risk for bacterial and fungal infection of the respiratory tract, which derive from their native flora from the donor lungs.

Pneumonia, the most important infectious complication, is difficult to differentiate from chronic colonization. Gram-negative pathogens and *S. aureus* can be recovered in the presence or absence of disease. Radiographic abnormalities are found almost universally for patients with pneumonia or graft rejection.[57–59] Bronchoalveolar lavage with transbronchial biopsy often is required to distinguish between causes.

Children undergoing lung transplantation because of CF have a high rate of infectious complications due to bacteria and fungi.[60] Patients usually are colonized with *Pseudomonas* or *Aspergillus* spp. Colonization with *Burkholderia cenocepacia* (formerly *B. cepacia* genomovar III) has been associated with excessive mortality rates.[61–63] BSI due to organisms present before transplantation is common after lung transplantation in these patients.[64,65] Because of the importance and difficulty in treating these bacterial complications, protocols at most transplantation centers include thorough interrogation of the microbial flora of candidates before transplantation, including evaluation of isolates of *B. cepacia* complex species at reference laboratories.

Fungal infection frequently complicates pediatric lung transplantation. Infections occur early and late after transplantation, particularly if patients develop BOS.[27,66] Many lung centers have instituted guidelines for fungal prophylaxis.[66,67]

Viral Infections

Viral pathogens, especially herpesviruses, are a major source of morbidity and mortality after SOT. Patterns of disease associated with individual viruses usually are similar among all transplant recipients. However, frequency, mode of presentation, and relative severity can be different according to the type of organ transplanted and the pretransplantation serologic status of the recipient.

Cytomegalovirus.

CMV remains one of the most common and important causes of viral infection after SOT. Infection can be asymptomatic or symptomatic and can be caused by primary infection, reactivation of latent CMV, or acquisition of a new CMV strain. Before the use of prophylaxis against CMV, the reported incidence of disease among children after transplantation was 22% for kidney,[68] 40% for liver,[11] and 26% for thoracic[9] organs. Preventive strategies and treatment with ganciclovir have resulted in decreased rates and severity of CMV disease.

Primary CMV infection, typically acquired from the donated organ, is associated with the highest morbidity and mortality rates. Reactivation of latent infection or superinfection with a new CMV strain tends to result in milder illness.[5] Patients treated with high doses of immunosuppressive agents, especially antilymphocyte products, have increased rates of CMV disease, regardless of previous immunity.[9,14,68]

CMV disease is characterized by the constellation of fever (which can be high grade, prolonged, and hectic) and hematologic abnormalities (including leukopenia, atypical lymphocytosis, and thrombocytopenia). Disseminated CMV disease, often referred to as *tissue invasive disease*, can cause signs and symptoms related to specific organ involvement. Common sites include the gastrointestinal tract, liver, and lungs. The site of involvement can vary according to the type of transplant.

CMV chorioretinitis is uncommon in SOT recipients. Before the availability of ganciclovir, fatal, disseminated CMV disease occurred in 4%, 14%, and 19% of infected children after kidney,[68] heart or heart-lung,[9] and liver transplantation,[11] respectively. Although death due to CMV is rare in the ganciclovir era, CMV viremia still is associated with an increased rate of death and retransplantation among pediatric lung transplant recipients.[69,70] CMV also is associated with a risk for secondary infections, rejection, and late graft loss in some adult series.[71]

Diagnosis of CMV disease is confirmed in a patient with a compatible clinical syndrome by means of quantitative nucleic acid based tests or, less frequently, by CMV pp65 antigenemia, histopathology, or culture.[16] However, results of viral cultures of urine and respiratory secretions (including bronchoalveolar lavage specimens) can be difficult to interpret because patients frequently shed CMV in these secretions asymptomatically. Quantitative tests have been valuable in predicting which patients are at risk for disease, allowing pre-emptive initiation of therapy. Past problems with interlaboratory variations in results led to the development and implementation of international standards.[71,72] Histologic examination of involved organs remains the gold standard to confirm the presence of invasive CMV disease.

Antiviral agents with activity against CMV (e.g., ganciclovir, valganciclovir, foscarnet, cidofovir) have improved dramatically the outcome of SOT recipients. For clinical CMV disease (i.e., fever with cytopenia or visceral disease), ganciclovir or valganciclovir is given in conjunction with a reduction of immunosuppression unless there is evidence of concurrent rejection. The clinical response usually occurs 5 to 7 days after treatment is begun. The duration of therapy is guided by serial measurements of the CMV viral load using quantitative assays.[29,71]

The role of CMV hyperimmune globulin in combination with ganciclovir in the treatment of CMV disease is controversial, although some evidence for improved outcome with combination therapy has been reported in the treatment of CMV pneumonia in adult transplant recipients.[73] Studies of the use of oral valganciclovir in adults have shown valganciclovir to be comparable to intravenous ganciclovir for clearance of viremia, and its use has been recommended for adults with mild to moderate CMV disease.[29,74] Although anecdotal reports of the use of oral valganciclovir for the treatment of CMV disease in pediatric transplant recipients are increasing, published data remain limited.[29]

The clinical response typically precedes the virologic response, especially when using sensitive nucleic acid amplification testing,[7] but resistance should be suspected in children whose tests fail to show any change by at least 14 days of therapy.[71] Confirmation of antiviral resistance in CMV infections should be confirmed using genotypic assays. Foscarnet and cidofovir use is restricted to patients with apparent or proven resistance to ganciclovir.

Epstein-Barr Virus.

EBV is an important cause of morbidity and mortality for pediatric

SOT recipients.[10,21,22,75,76] A wide spectrum of EBV disease is recognized, including nonspecific viral illness, mononucleosis, and PTLDs, including lymphoma. Histologic evaluation is important in differentiating among these categories, and manifestations can evolve in individual patients. Asymptomatic seroconversion also occurs.

Variation in severity and extent of disease is related to the degree of immunosuppression and adequacy of the host immune response. Symptomatic EBV infection in general and PTLD in particular are more common after primary EBV infection, affecting children disproportionately.[6] In one study, 4% of children undergoing SOT and 10% of children with primary EBV infection developed PTLD between 1 month and 5 years after transplantation.[6] In the absence of preventive interventions, cumulative occurrence can be as high as 12% to 20% by 7 to 12 years after liver transplantation.[30,77] The onset of a viral syndrome, mononucleosis, and PTLD occurs primarily within the first year after transplantation, whereas lymphoma tends to occur later. The introduction of new immunosuppressive agents and regimens invariably impacts the incidence and timing of EBV disease.[78–80] Careful monitoring of patients receiving newer regimens is warranted.

The diagnosis of EBV-associated PTLD is made on the basis of clinical, laboratory, and histopathologic findings and should be suspected in patients with protracted fever, exudative tonsillitis, lymphadenopathy, organomegaly, leukopenia, or atypical lymphocytosis (see Chapter 208).[21,22] Gastrointestinal involvement should be suspected in patients with persistent fever and diarrhea.

The serologic diagnosis often is confounded by the presence of passive antibody. Quantitative EBV polymerase chain reaction (PCR) assays to predict risk for or presence of EBV viremia or PTLD are used widely.[22,81–83] Although extremely sensitive, these assays lack specificity; the viral load often is elevated in asymptomatic patients.[84] Every effort should be made to confirm the diagnosis of EBV disease or PTLD histologically.

Occult sites of PTLD are assessed with computed tomography of the chest and abdomen. Data suggest a potential role for position-emission tomography (PET). Palpable nodes or lesions identified by imaging should be biopsied. Endoscopy should be considered in patients with an elevated viral load and diarrheal illnesses.

Histologic evaluation can be augmented through the use of the Epstein-Barr–encoded RNA (EBER) probe.[85]

Guidelines for the management of patients with EBV disease and PTLD recommend a stepwise approach to therapy, starting with reduced immunosuppression. Further escalation of treatment is based primarily on the patient's clinical response and the histopathologic characteristics of the PTLD lesion.[86] Although antiviral agents and immune globulin intravenous (IGIV) are used frequently as part of this initial strategy,[81,87] their efficacy in the treatment of EBV-associated PTLD has not been established. Reduction of immunosuppression, alone or in combination with antiviral therapy, results in an approximately 67% cure rate of EBV-associated PTLD.

For patients who fail to respond to the initial approach, two alternative treatment strategies have been proposed. Rituximab, an anti-CD20 antibody, has been used increasingly for the treatment of EBV disease.[86] Experience suggests that as many as two thirds of patients who fail to respond after the initial withdrawal of immunosuppression respond to a 4-week course of rituximab.[88,89] However, relapse of EBV disease has been observed in 20% to 25% of treated patients 6 to 8 months after completion of therapy, at the time when rituximab antibody has waned. The second alternative for patients failing initial reduction or withdrawal of immunosuppressive therapy is the use of modified doses of cyclophosphamide and prednisone; therapy is successful in approximately two thirds of patients.[90] Unfortunately, relapse of PTLD has occurred in 22% of treated patients, and outright treatment failures have occurred in patients with fulminant disease. The addition of rituximab to this protocol improved outcomes of patients with fulminant disease, but relapses occur.[91] Studies comparing these second-line therapies are needed to define optimal treatment for children who fail initial modification of immunosuppression.

Cytotoxic chemotherapy should be considered for patients who fail to respond to the stepwise approach. It can be considered as first-line therapy for those with T-lymphocyte–associated PTLD, PTLD of the central nervous system, and monomorphic PTLD occurring late in the posttransplantation course.[86]

Adenovirus.

After pediatric liver transplantation, adenovirus is the third most important viral infection, occurring in 10% of recipients in one large early series.[92] Symptomatic disease, which ranges from self-limited fever, gastroenteritis, and cystitis to devastating illness with necrotizing hepatitis or pneumonia, occurred in more than 60% of infected patients. Infections occurred within the first 3 months after transplantation. The frequency of invasive adenovirus infections after pediatric liver transplantation appears to have decreased with the use of tacrolimus-based immunosuppression. This may reflect the ability to decrease the overall amount of immunosuppressive agents.[93,94]

Adenovirus infection in other pediatric organ recipients is less well characterized but can be severe, particularly after lung transplantation, and it can be fatal when disease manifests soon after transplantation.[27,95–98] Adenovirus DNA found in cardiac biopsies after pediatric heart transplantation was significantly associated with poor graft survival in one series.[99] Adenovirus also has been associated with hemorrhagic cystitis and graft dysfunction in adult renal transplant recipients.[100] High rates of adenovirus infection have been found after pediatric intestinal transplantation, although clinical disease does not always occur.[94,100–103]

The diagnosis of adenovirus infection can be challenging as this virus, like CMV, can be latent and can reactivate asymptomatically. Ascribing a causative role in the pathologic process sometimes is difficult. The use of nucleotide amplification testing (NAT) to detect adenovirus in the peripheral blood or other sites (e.g., bronchoalveolar lavage) can be helpful or confusing because adenovirus can be detectable in blood or other body fluids in the absence of clinical disease. Definitive diagnosis of adenovirus disease is made by histologic evidence of the virus by direct inspection of typical inclusions or immunofluorescent antibody, or both.[102]

Although no antiviral agent is approved for the treatment of adenovirus, many experts consider cidofovir to have clinical antiviral activity against the virus. Brincidofovir (i.e., liposomal derivative of cidofovir) is undergoing formal evaluation in clinical trials for the treatment of adenovirus infection.[102]

Varicella-Zoster Virus.

Many children have undergone SOT without immunity against VZV. Early experience found severe and potentially fatal disease in children developing varicella infection after transplantation.[104,105] Some fatal cases occurred despite the use of intravenous acyclovir, and disease developed in approximately 50% of patients who received postexposure varicella-zoster immune globulin (VZIG). Recently, few or no patients have developed significant complications of VZV infection after SOT.[28,106] These results were achieved in children treated with acyclovir intravenously, although a small subset thought to be at low risk for severe disease were treated with oral acyclovir or valacyclovir.

Current recommendations favor an aggressive response to varicella exposure and disease.[107] Administration of VariZIG is recommended up to 10 days after exposure of nonimmune patients; administration as soon as possible is preferred. Alternatives include the use of an intravenous immunoglobulin or off-label use of oral acyclovir or valacyclovir starting at day 7 after a known exposure date or starting as soon as possible if the date of exposure is not known (unpublished data). If varicella lesions develop, it is prudent to hospitalize patients and administer acyclovir intravenously until fever abates, no new lesions erupt, and existent lesions begin to crust.[108] Some centers have managed patients with mild disease using oral acyclovir or valacyclovir in the outpatient setting when close follow-up can be ensured.

The use of VZV vaccine after SOT is an area of active research. Limited experience in pediatric renal[109] and liver transplant recipients[109] is encouraging. Immunogenicity and safety appear to be acceptable in children who are more than 1 year out from transplantation and who have stable and relatively low levels of immunosuppression. However, these patients have received vaccine under study protocols with close follow-up, and 25% had vaccine-associated rash, prompting antiviral therapy.[109] Additional experience is needed before recommending a standard protocol for VZV vaccination after transplantation.

Common Community-Acquired Viruses.

Limited published data suggest that most children who receive SOT experience the usual childhood respiratory and gastrointestinal tract illnesses without significant problems.[7,50] This is especially true when they occur long after transplantation and are not associated with an episode of rejection.[7] However, infections caused by respiratory syncytial virus (RSV), influenza virus, or parainfluenza virus (PIV) have led to more severe disease in young children, especially when occurring soon after transplantation and during periods of maximal immunosuppression.[110,111]

A retrospective review of 576 pediatric lung transplant recipients from 14 centers found that 79 (14%) patients who had confirmed respiratory virus infections during the first year had a decreased 1-year survival rate.[97] Shirali and colleagues found that DNA from community-associated viruses such as enterovirus, adenovirus, and parvovirus in heart biopsies of children after cardiac transplantation was associated with increased adverse events, but the timing of the biopsies relative to the time of transplantation was not evaluated.[98]

Opportunistic Infections

Pneumocystis jirovecii Pneumonia.

Pneumocystis pneumonia (PCP) is a well-documented complication of SOT. Before the introduction of prophylaxis, the incidence of PCP was 4% to 35%.[23–25] However, use of TMP-SMX prophylaxis has essentially eliminated this problem.

PCP typically occurs after the first month after transplantation, reflecting indolent infection before transplantation. Most cases occur within the first year after transplantation, but PCP can occur later and should remain in the differential diagnosis for patients with fever and lower respiratory tract symptoms, particularly if they are not receiving PCP prophylaxis.

Toxoplasmosis.

Toxoplasma gondii can cause significant infection in immunocompromised hosts.[112] A rare cause of disease in renal and liver transplant recipients,[113] toxoplasmosis more often is an infectious complication after cardiac transplantation.[26,114] The risk for cardiac recipients may be explained by tropism of the organism for cardiac muscle and subsequent donor transmission.

Reactivation of cysts within the graft occurs in the immunosuppressed recipient without previous immunity. This contrasts with adult patients with AIDS who develop reactivation disease despite the presence of antibody.

Clinical manifestations usually occur 2 to 24 weeks after transplantation and include fever, pulmonary disease, chorioretinitis, myocarditis, and neurologic disorders. Use of pyrimethamine or TMP-SMX prophylaxis has been effective in adult patients.[115,116]

Tuberculosis.

Tuberculosis is a special concern in immunosuppressed hosts, including SOT recipients. Although the development of tuberculosis is rare in US centers, an incidence of 2.4% was reported from a pediatric liver transplantation center in the United Kingdom.[117] Although most cases in this series were thought to represent primary infection acquired after transplantation, transplant recipients with a reactive tuberculin skin test (TST) result or who come from areas where tuberculosis is endemic are at increased risk for symptomatic reactivation.[118–120] The risk of reactivation tuberculosis appears greatest for patients who received no, inadequate, or incomplete prior treatment for latent infection.

A careful history of exposure, a TST, or an interferon γ release assay (for children >5 years of age)[121] and a chest radiograph are evaluated before transplantation. Patients with latent tuberculosis who received no or inadequate treatment should receive isoniazid for at least 9 months after transplantation.[117,122] When possible, treatment should begin before transplantation. Attempts at a more definitive diagnosis are indicated for a patient from an endemic area who has a negative TST result but a suspicious radiograph. Combination-drug antituberculosis therapy is indicated for those thought to have disease due to *Mycobacterium tuberculosis*. Evidence of side effects, particularly hepatotoxicity, should be monitored carefully in all pediatric transplant recipients receiving therapy for tuberculosis.

Other Opportunistic Infections.

Endemic fungal infections such as coccidioidomycosis and histoplasmosis are concerns for patients with exposure to specific geographic areas. Parasitic infections (e.g., *Trypanosoma cruzi*) have occurred in adult transplant recipients. Because patients often travel to transplantation centers distant from their homes, physicians caring for SOT candidates or recipients must be cognizant of the environmental risks for each patient. Experience with coccidioidomycosis in transplant recipients suggests that a minimum of 4 months of antifungal therapy, such as fluconazole, should be given to transplant recipients with this history.[123]

Management and Preventive Measures

Pretransplantation Evaluation

Pretransplantation evaluation permits preventive intervention and anticipation of posttransplantation complications. A history should be obtained and a physical examination performed with particular attention to previous infections, exposures, immunizations, and drug allergies. Children with CF or those with a prolonged stay under intensive care just before transplantation can be colonized with antimicrobial-resistant organisms. Pretransplantation surveillance cultures are useful in guiding subsequent empiric selection of antimicrobial agents in these patients.

Screening for tuberculosis is performed along with serologic studies for CMV, EBV, HSV, VZV, HBV, HCV, HIV, and syphilis. Other serologic tests, such as for *T. gondii* (particularly for heart transplant candidates) and hepatitis A serology for liver transplant candidates, should be performed. Donor serologic testing is performed for microbes proved to be transmitted by blood or organs (Tables 95.2 and 95.3). WNV has been transmitted by organ donation from undiagnosed cases, resulting in severe disease in the recipient. Currently, blood donor screening but not organ donor screening by WNV nucleic acid amplification test is performed routinely.[124] However, screening should be considered in specific geographic areas during periods of WNV activity.

TABLE 95.2

Screening Tests for Transplant Candidates[a]

Test and Pathogen	Comment
SEROLOGIC TESTS[b]	
HIV-1 and -2	
HTLV-1 and -2	
Hepatitis A virus	IgG and IgM screening test
Hepatitis B virus	Hepatitis B surface antigen and anti–core antibody indicate active disease; anti–hepatitis B surface antigen indicates serologic conversion after immunization
Hepatitis C virus	
Hepatitis D virus	Test if hepatitis B virus positive
CMV	IgG test; urine culture if positive
EBV	Antiviral capsid antigen IgG and EBNA
Herpes simplex virus	
Varicella-zoster virus	If history of age-appropriate vaccinations, confirmed disease, or serology is negative, consider age-appropriate immunizations, the last ≥4 weeks before anticipated transplantation
Toxoplasma gondii	Obtain for heart and heart-lung transplant candidates in particular; some centers screen all candidates
Measles virus	If serology is negative, consider immunization if ≥4 weeks anticipated before transplantation
Mumps virus	If serology is negative, consider immunization if ≥4 weeks anticipated before transplantation
Rubella virus	If serology is negative, consider immunization if ≥4 weeks anticipated before transplantation
OTHER TESTS	
Mycobacterium tuberculosis	Tuberculin skin test (TST) and/or interferon γ release assay (IGRA)
Respiratory tract pathogens	Sputum culture for patients with cystic fibrosis and other lung transplant candidates

[a] All tests performed on all candidates except where noted.

[b] IgG antibody measured except where noted.

CMV, cytomegalovirus; EBNA, Epstein-Barr virus nuclear antigen; EBV, Epstein-Barr virus; HIV, human immunodeficiency virus; HTLV, human T-lymphotropic virus; Ig, immunoglobulin.

TABLE 95.3

Recommended Screening Using Serologic Testing or Nucleotide Amplification Testing of Organ Donor[a]

Pathogen	Comment
HIV-1 and -2	Positive result contraindicates organ use (fourth-generation HIV antigen/antibody allowed for all donors in the US. HIV NAT *or* combined HIV antigen/antibody testing required for donors at increased risk for HIV, HBV, and/or HCV in the US)
Hepatitis A virus	Positive result for IgM test contraindicates organ use
Hepatitis	Obtain HBV core antibody and HBV surface antigen; result suggesting current

B virus	infection contraindicates organ use
Hepatitis C virus	Some centers use positive donor only for positive candidate (HCV NAT required on all donors in US)
CMV	Obtain IgG test; obtain urine culture if positive neonatal donor
EBV	Obtain antiviral capsid IgG and IgM
Toxoplasma gondii	Obtain for heart and heart-lung donors in particular
Treponema pallidum	Obtain treponemal-specific assays, followed by reagin test (specific test if positive) or regain test alone; positive result contraindicates organ use

[a] IgG antibody measured except where noted.

CMV, cytomegalovirus; EBV, Epstein-Barr virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; Ig, immunoglobulin; NAT, nucleotide amplification testing; US, United States.

Strategies should be implemented to optimize immunizations during the pretransplantation period. This is particularly relevant for young organ transplant candidates who may not have completed their primary vaccination series. These infants should start vaccinations at 6 weeks of age and follow an accelerated schedule.[125] Immunizations sometimes are delayed and often overlooked while these children are waiting for transplantation because of their medical conditions. Despite their underlying illnesses, vaccine responses are likely to be better in the transplant candidate than in the transplant recipient.[126]

Inactivated and purified antigen vaccines are given to maximize protection before immunosuppression. Influenza vaccine should be given to children 6 months of age or older and to all family members. After receipt of pneumococcal conjugate vaccines (e.g., PCV13), 23-valent pneumococcal polysaccharide vaccine (PPSV23) should be given to those 2 years of age or older.[127] Children expected to have at least 4 weeks before transplantation should be given live virus vaccines at the earliest ages recommended.

In many centers, immunologic response is assessed by serologic testing, at least for measles, mumps, and varicella. If seroconversion is not documented, revaccination can be attempted if time permits. Living donors should be current with vaccines based on age, vaccination history, and exposure history according to the Centers for Disease Control and Prevention (CDC) annual schedule. Live virus vaccines should be avoided within 4 weeks of organ donation.[127]

Preventive Strategies

Antimicrobial and Immunoglobulin Prophylaxis

Prophylactic regimens for SOT vary by center and type of transplant. Perioperative antibiotics are used for the first 48 to 72 hours to provide protection against intraoperative soilage, septicemia, and wound infection. The choice of antimicrobial agents is dictated by the organ being transplanted, patient characteristics, expected flora, and knowledge of the antimicrobial susceptibilities of local pathogens and the patient's flora if known. Surveillance cultures of the donor bronchi or trachea also are useful in heart-lung or lung transplantation. CF patients usually require a more prolonged period of prophylaxis.

The frequency and severity of CMV infections in transplant recipients prompt consideration of prophylactic strategies.[128] Although published guidelines provide evidenced-based recommendations for adult organ transplant recipients,[29,71,129–131] definitive data to inform recommendations for pediatric SOT recipients are not available. Accordingly, various strategies are used.[132]

The CMV prevention strategies used at the Children's Hospital of Pittsburgh (CHP) vary by organ type and the donor and recipient status. All pediatric recipients deemed to be at risk for CMV disease are begun at transplantation on intravenous ganciclovir; oral valganciclovir is considered for those requiring prophylactic therapy beyond 2 weeks. High-risk (i.e., CMV-positive donor and CMV-negative recipient) intestinal transplant recipients also receive CMV IGIV at CHP.

At the completion of prophylaxis, many recipients undergo serial monitoring by quantitative blood PCR testing in what some experts have called a *hybrid* or *sequential prevention approach*. Change of virus density over time is more useful than a quantitative cutoff point. Serial quantitative monitoring of the blood CMV load (or less commonly, pp65 antigenemia assays) from the time of transplantation also has been used to inform the use of pre-emptive antiviral therapy.[71,133] In this approach, only patients demonstrating an increasing viral load are treated. Although this strategy has gained acceptance at some centers, experience in pediatric transplant recipients remains limited.

Several strategies are being explored (e.g., immunoprophylaxis, monitoring, pre-emptive therapy) to prevent EBV-associated

PTLD.[134–136] Their relative efficacies have not been established. Serial monitoring of the viral load to inform pre-emptive reductions in immunosuppression appears to be the most promising strategy.[136]

Nystatin suspension can be used in pediatric transplant recipients for the first 3 months after transplantation to prevent oropharyngeal candidiasis. TMP-SMX is used to prevent PCP. When given on a daily basis, the use of TMP-SMX also decreases the incidence of posttransplantation UTI in renal transplant recipients.[32] The duration of prophylaxis for PCP is controversial. Most cases occur during the first year after transplantation. However, because late cases occur, TMP-SMX is given indefinitely at some centers. Fungal prophylaxis against *Aspergillus* is used for children undergoing lung transplantation for various durations.

Immunizations After Transplantation

Centers use various protocols for immunization after transplantation.[137,138] The decision about when to initiate immunizations after organ transplantation should be individualized. For some patients, induction immunosuppression or recurrent treatment of rejection may require a prolonged delay in starting immunizations due to significant ongoing immunosuppression. For others who have an uncomplicated posttransplantation course, immunizations with inactivated agents may be resumed as early as 3 to 6 months after transplantation, depending on baseline immunosuppression. However, earlier use of inactivated influenza vaccine should be considered for children who were not immunized before transplantation and who undergo transplantation just before or during the influenza season.

Live vaccines usually are not administered after transplantation, although several small clinical trials evaluating the measles, mumps, and rubella (MMR) and varicella vaccines demonstrated promising safety profiles.[109,138–142] There are insufficient data regarding the safety of rotavirus vaccines to recommend their use after transplantation, and limitations of age at commencement exclude most SOT recipients from consideration.

Infections in Hematopoietic Stem Cell Transplant Recipients

Jorge Luján-Zilbermann, David M. Berman

Hematopoietic stem cell transplantation (HSCT) has broad indications in pediatrics, including treatment of cancer, primary immunodeficiency syndromes, bone marrow failure syndromes, hemoglobinopathies, and an assortment of genetic conditions, including inborn errors of metabolism, and nonmalignant conditions such as osteopetrosis.[1–3] Patients undergoing HSCT have increased risks of infections that are somewhat predictable based on the acquired immune deficiencies that occur after HSCT.[4–7]

Etiologic Agents

Patients who have had HSCT have immune deficiencies in the phagocytic, humoral, and cellular arms of the immune system.[4] These immune defects lead to pathogen susceptibility and infectious complications in three predictable risk periods (Fig. 96.1).[4] After the conditioning regimen, a period of neutropenia occurs for 3 to 4 weeks, during which bacteria and fungi cause most infections. Herpes simplex virus (HSV) and seasonal respiratory viral infections also can occur.[4,7,8]

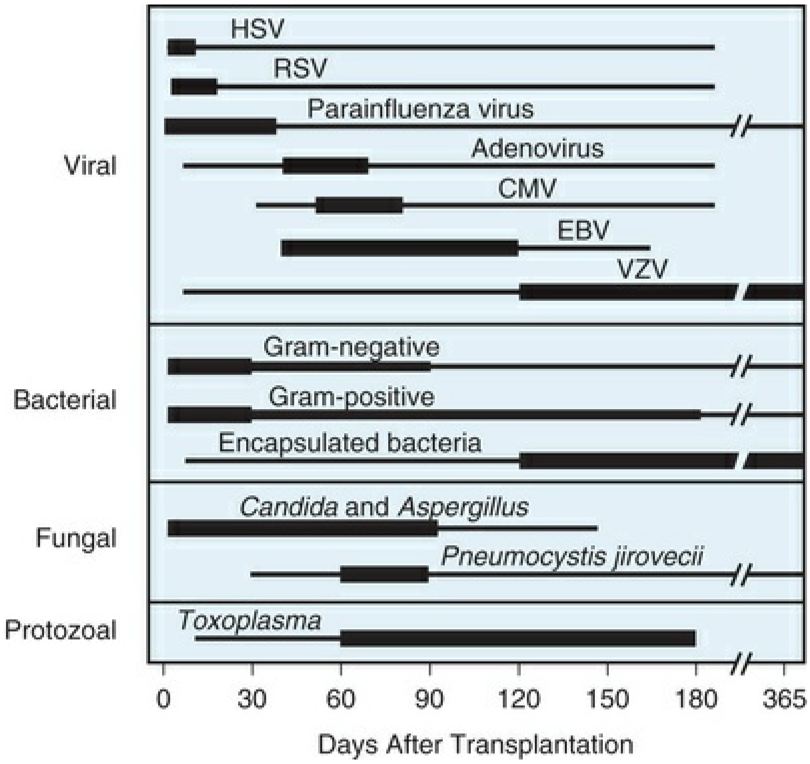

FIGURE 96.1 Temporal association of infectious agents and hematopoietic stem cell transplantation. Day 0 is the time of stem cell infusion. *Boldness* of the line denotes increasing frequency of infection with the offending agent. CMV, cytomegalovirus; EBV, Epstein–Barr virus; HSV, herpes simplex virus; RSV; respiratory syncytial virus; VZV, varicella–zoster virus.

The middle period occurs after granulocyte recovery and continues until approximately 100 days after HSCT. Infectious complications during this period are associated with profound impairment of humoral and cellular immunity. Although bacterial and fungal infections still can occur, they are much less frequent than during the neutropenic period. Cytomegalovirus (CMV) is a major infecting agent, but *Pneumocystis jirovecii* disease also can occur. With the advent of effective prophylaxis against both of these agents, the incidence of associated disease has decreased. Infections due to adenovirus and Epstein–Barr virus (EBV) can occur, especially with the use of mismatched HSCT and T-lymphocyte–

depleted HSCT.[9–11]

The late period is associated with deficits in humoral immune responses, cellular immune responses, and reticuloendothelial function begins 100 days after HSCT. Varicella-zoster virus (VZV) and encapsulated bacteria, particularly *Streptococcus pneumoniae* and *Haemophilus influenzae* type b (Hib), are major pathogens during this period.

Epidemiology

Among HSCT recipients, most infections are derived from their microbial flora or reactivation of latent infections. Many factors account for the high risk of infectious complications among HSCT recipients (Box 96.1). Immune deficiency associated with the underlying disease is a determinant of the degree of immune suppression.

Box 96.1

Predisposing Factors for Infectious Complications in Hematopoietic Stem Cell Transplant Recipients

- Underlying illness
- Type of transplant
- Conditioning regimen
- Infectious disease history
- Indwelling medical device
- Occurrence and severity of graft-versus-host disease
- Immunosuppressive regimen administered to prevent graft-versus-host disease
- Epidemiology of infection in hospital or transplantation care unit

Allogeneic HSCT recipients (i.e., matched unrelated donor or unrelated cord blood transplantation) are at high risk for graft-versus-host disease (GvHD), which enhances the infection rate by delaying the return of normal immune function and by ulceration of the gastrointestinal tract. Moreover, the risk of infection is directly related to the degree of donor-recipient mismatch. To abrogate GvHD, immune-suppressing medications are administered as prophylaxis. These agents increase the risk of infection by depressing the cell-mediated immune response and by disrupting mucosal barriers.

The conditioning regimen with or without concomitant irradiation compromises the immune system and can disrupt mucosal barriers. Purging of the bone marrow in autologous transplants to reduce the load of malignant cells and T-lymphocyte depletion used in allogeneic transplants to reduce the incidence of GvHD predispose the host to infection.

The serologic status of the donor and the recipient is important because many infections in transplant recipients are caused by reactivation (Table 96.1). This is most notable for the herpesviruses. CMV is a major cause of pneumonitis in allogeneic transplant recipients. Other herpesviruses, especially HSV, VZV, and EBV; *Toxoplasma gondii*; and adenovirus infections are prone to reactivate after the transplantation.

TABLE 96.1

Evaluation of Patients Before Hematopoietic Stem Cell Transplantation

Study Type	Organism or Test
Serum antibody assay	CMV
	EBV
	HSV
	VZV
	Hepatitis B (HBsAg, HBsAb, HBcAb)
	Hepatitis C
	RPR
	Human immunodeficiency virus
Other laboratory tests	Serum hepatic enzymes (ALT, AST, bilirubin)
	Renal function tests (BUN, creatinine)
	Complete blood cell count with differential leukocyte count
	Stool for ova and parasites
Tuberculosis test	Tuberculin skin test (TST); for children >5 years of age, interferon γ release assay (blood) is acceptable
Radiographic testing	Chest, posteroanterior and lateral
	Sinus series, if clinically indicated

ALT, alanine aminotransferase; AST, aspartate aminotransferase; BUN, blood urea nitrogen; cAb, core antibody; CMV, cytomegalovirus; EBV, Epstein–Barr virus; RPR, rapid plasma reagin; sAb, surface antibody; sAg, surface antigen.

All HSCT recipients have a central venous catheter (CVC) placed before transplantation, providing a potential site for infection. Patients who have other indwelling medical devices (e.g., cerebrospinal fluid shunts) have an increased risk of infection. Patients with a history of invasive aspergillosis who are undergoing HSCT require adequate antifungal prophylaxis and treatment to prevent relapse of the disease.[12]

Knowledge of the epidemiology of pathogens associated with the local hospital and the transplantation unit allows assessment of the risk of environmental organisms such as *Aspergillus* and *Legionella* species. Rates of infection can be reduced substantially by preventive mechanisms that inhibit aerosolization of organisms, such as the use of laminar flow rooms or high-efficiency particulate air (HEPA)–filtered rooms.[6]

Clinical Syndromes, Differential Diagnosis, and Clinical Approach

The approach to a patient who has had HSCT takes into account the infections that can occur during each of the risk periods (see Fig. 96.1). This provides the framework for matching possible causative agents with the clinical syndrome. Because some of these clinical syndromes are highlighted in Chapters 97 and 98, the following discussion focuses on the clinical approach to the HSCT recipient.

Early Period

Several types of infection are more likely to occur during the early period (i.e., before engraftment) of the transplantation process.

Herpes Simplex Virus Gingivostomatitis.

HSV infection occurs primarily as a result of reactivation in seropositive patients undergoing HSCT. The diagnosis is difficult because lip lesions are rare and mucosal ulcerations are similar to those that occur as a result of the conditioning regimen.

Central Venous Catheter–Related Bloodstream Infections.

During the neutropenic period, HSCT recipients are at high risk for bacterial infection, comparable with the risk for patients with cancer who develop chemotherapy-induced neutropenia. Central line–associated bloodstream infections (CLABSIs) are common because of the uniform use of indwelling CVCs in HSCT patients for administration of medications, hyperalimentation, blood products, and blood sampling. Measures to prevent CLABSIs should be followed.[6,13]

Staphylococcus epidermidis and other coagulase-negative staphylococci are the most common causes of bloodstream infections (BSIs) during the three periods after transplantation.[14–16] Other gram-positive organisms associated with BSIs in HSCT recipients include viridans streptococci and *S. aureus.*[14–16] Viridans streptococci infections have been associated with chemotherapy-induced mucositis and poor dental hygiene.[17,18] Most gram-positive catheter-related infections can be treated successfully without removal of the catheter.

Gram-negative bacillary infections occur after mucosal damage with bacterial translocation from the intestinal mucosa into the bloodstream and are the second most frequent cause of BSI. The predominant organisms in this class include *Escherichia coli, Klebsiella* spp., and *Pseudomonas aeruginosa,* although other gram-negative organisms are common.[14,16] Antibiotic resistance among these organisms is common. Catheter-related infections with some gram-negative bacilli, *Candida* spp., and *Bacillus cereus* can be problematic and require catheter removal.

Fungal Infections.

The major causes of fungal infection include *Aspergillus* spp., *Candida* spp., and agents of mucormycosis (e.g., *Mucor, Absidia, Rhizopus* spp.).[19–21] Other fungi recognized as pathogens include *Trichosporon* spp., *Fusarium* spp., *Curvularia* spp., and *Alternaría* spp.[21–23] Infection with these organisms usually occurs after a period of antibiotic therapy and correlates with the degree and duration of neutropenia. Although *Candida albicans* is the most frequent *Candida* species causing BSI, *C. tropicalis* may cause more severe disease. Other *Candida* species, including *C. glabrata, C. parapsilosis,* and *C. krusei,* also have emerged because of resistance to fluconazole, which is used as prophylaxis.[20–22]

The portal of entry for *Aspergillus* and agents of mucormycosis is the respiratory tract, as opposed to that for *Candida* spp., which is the gastrointestinal tract. *Aspergillus* is associated with sinopulmonary disease and dissemination (Fig. 96.2), but it is rarely recovered from blood cultures. Diagnosis usually depends on tissue histology and culture of material obtained from bronchoscopy, lung aspiration, or open-lung biopsy. The galactomannan assay can be useful in the early diagnosis of invasive aspergillosis in high-risk patients.[12,24]

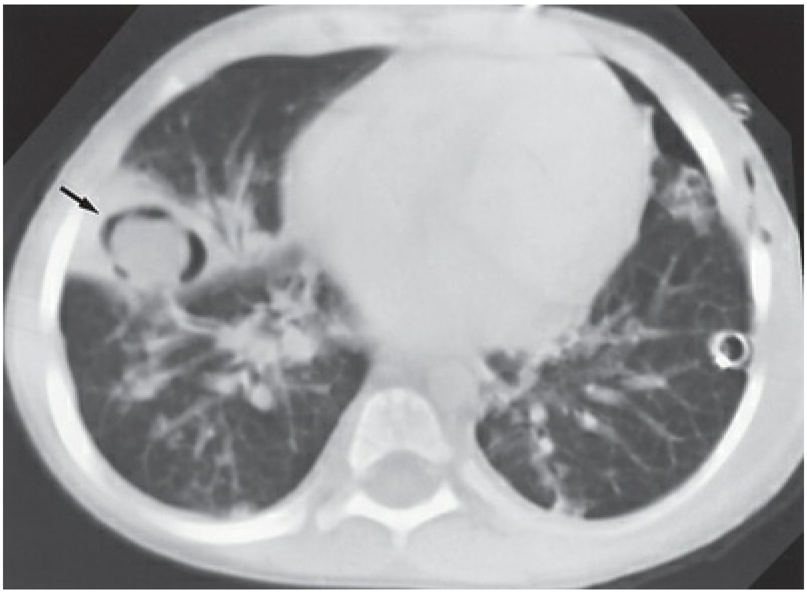

FIGURE 96.2 Invasive aspergillosis in a patient after hematopoietic stem cell transplantation. Computed tomography of the chest shows bilateral pulmonary involvement, including aspergilloma in the right middle lobe *(arrow)*.

Hemorrhagic Cystitis.

Hemorrhagic cystitis is associated with a variety of infectious and noninfectious causes (Box 96.2).[25] The onset can occur at any time during the transplantation period; chemotherapy-induced cystitis occurs soon after commencing the conditioning regimen. The most common infectious causes are polyomaviruses (BK virus and JC virus) and adenovirus.[25–27] Bacterial and fungal pathogens also must be considered.

Box 96.2

Differential Diagnosis of Hemorrhagic Cystitis in Hematopoietic Stem Cell Transplant Recipients

Infectious Causes

Virus

Adenovirus

Cytomegalovirus

Polyomaviruses, especially BK virus and JC virus

Herpes simplex virus

Bacteria

Urinary tract infection, predominantly gram-negative bacilli

Fungus

Urinary tract infection

Fungus ball

Noninfectious Causes

Chemotherapy (e.g., cyclophosphamide)

Graft-versus-host disease

Mechanical trauma from Foley catheter

Enteric Infections.

Diarrhea after transplantation is caused most commonly by mucositis and GvHD. Enteric infections can occur throughout the transplantation period. Antibiotic-associated diarrhea, including that due to *Clostridium difficile,* usually occurs during the neutropenic period, when antimicrobial agents are frequently administered. Other infecting agents, including enteric adenovirus, rotavirus, coxsackievirus, and noroviruses, should also be considered.[11,28] Infections caused by enteric viruses typically are seasonal in occurrence.

Middle Period

The middle period (i.e., early engraftment), which spans days 30 through 100 after transplantation, was once was dominated by CMV infection, but the incidence of CMV infection has diminished with the use of ganciclovir as pre-emptive therapy. Bacterial infections are less problematic during this period, except for those associated with indwelling catheters. Fungal infections occur in patients with GvHD.

Pneumonitis.

Pulmonary infiltrates can have infectious or noninfectious causes (Box 96.3). Although signs and symptoms can occur throughout the transplantation period, viral infections are more common during the early engraftment period.

Box 96.3

Causes of Pneumonitis in Hematopoietic Stem Cell Transplant Recipients

Infectious Causes

Bacteria

- Enterobacteriaceae
- *Staphylococcus aureus*
- *Legionella pneumophila*

Fungi

- *Aspergillus* species
- Mucormycosis
- *Pneumocystis jirovecii*

- *Candida* species

Viruses

- Parainfluenza types 1–4
- Adenovirus
- Respiratory syncytial virus
- Human metapneumovirus
- Cytomegalovirus
- Influenza
- Human herpesvirus 6
- Coxsackievirus and echoviruses
- Rhinovirus

Noninfectious Causes

Pulmonary damage by radiation exposure

Pulmonary damage by chemotherapeutic agents (e.g., bleomycin)

Underlying cancer

Pulmonary edema

Alveolar hemorrhage

Idiopathic interstitial pneumonia

Pulmonary vascular disease

Pneumomediastinum

CMV manifests at a median time of 40 to 50 days after the transplantation period (see Fig. 96.1). CMV most commonly occurs because of reactivation of latent virus in seropositive individuals but also can occur in seronegative patients who receive a transplant from a seropositive donor. Risk factors for CMV pneumonia include seropositivity of the donor, type of transplant (i.e., allogeneic more than autologous), human leukocyte antigen (HLA)–mismatched transplant, older age of the patient (>10 years), and development of acute GvHD.[29]

CMV infection occurs in 30% to 50% of patients undergoing HSCT; pneumonia occurs in 10% to 15% of these patients and has a mortality rate of 85%. CMV infection and disease also occur in autologous HSCT recipients, although at a much lower incidence. The clinical manifestations of CMV disease vary from asymptomatic infection to the constellation of fever, hepatitis, and leukopenia to life-threatening diseases such as interstitial pneumonitis, esophagitis, and encephalitis.[30]

Other viral causes of respiratory tract infections include adenovirus, respiratory syncytial virus (RSV), human metapneumovirus, parainfluenza virus, influenza virus, human herpesvirus 6 (HHV-6), coxsackievirus, and rhinovirus.[31–37] RSV, influenza virus, and parainfluenza virus can cause sinusitis and life-threatening pneumonia.[31,32,37]

Pneumocystis jirovecii also causes pneumonia after engraftment.[38] Clinical manifestations are similar to those in other immunocompromised hosts. The incidence of *Pneumocystis* pneumonia (PCP) has been curtailed markedly by routine prophylaxis with trimethoprim-sulfamethoxazole (TMP-SMX) and pentamidine.

Adenovirus Infection.

Adenovirus infection occurs in approximately 30% of pediatric HSCT recipients and can become latent in lymphoid tissue and kidneys.[39] The most common clinical manifestations of infection include diarrhea, febrile illness, hemorrhagic cystitis, and pneumonia but also can include hepatitis and encephalitis.[39]

Toxoplasmosis.

Toxoplasmosis is a rare but almost always fatal infection after HSCT. Toxoplasmosis usually occurs 2 to 6 months after HSCT, and the central nervous system is affected most often. Symptoms include focal neurologic signs, fever, seizures, and altered mental status. Imaging of the brain typically shows multiple lesions in both hemispheres and the basal ganglia.[40,41]

Encephalopathy.

Encephalopathy is a poorly characterized complication of HSCT. It has a very poor prognosis for pediatric patients, with a mortality rate of 65% in one study.[42] Several infectious and noninfectious causes have been described (Box 96.4).[33,41,42] HHV-6 has been associated with encephalitis and delayed platelet engraftment.[35,36,43]

Box 96.4

Differential Diagnosis of Meningitis, Encephalitis, and Encephalopathy in Hematopoietic Stem Cell Transplantation Recipients

Infectious Causes

Viruses

- Adenovirus
- Human herpesvirus 6 and 7
- Polyomaviruses, especially BK virus and JC virus (progressive multifocal leukoencephalopathy)
- Herpes simplex virus and varicella-zoster virus
- Postviral (acute disseminated encephalomyelitis)

Bacteria

- *Streptococcus pneumoniae*

Fungi

- *Aspergillus* species

Protozoa

- *Toxoplasma gondii*

Noninfectious Causes

Medications (e.g., cyclosporine, amphotericin B)

Nonconvulsive seizures

Thrombotic thrombocytopenic purpura

Multiorgan system failure

Stroke

Late Period

At 100 days after transplantation, the late period begins. It lasts for 6 to 12 months or longer, depending on the complications of transplantation, especially GvHD.

Bloodstream Infection.

Bacterial infections occur less commonly during the late period, but patients continue to be immunosuppressed and susceptible to bacterial infection and BSI. Chronic GvHD augments this immunosuppression. Encapsulated bacteria, especially *S. pneumoniae* and Hib, are the most common agents responsible for bacterial infections that are not related to the existence of an indwelling catheter.[4]

Varicella-Zoster Virus Infection.

VZV infections occur in 25% to 40% of patients after HSCT.[44] Reactivation occurs more frequently in association with chronic GvHD but also has been described in patients after autologous HSCT. A prodrome of a burning sensation or pain over the involved dermatome can occur. Groups of vesicles appear in the distribution of one to three sensory dermatomes. If appropriate therapy with acyclovir is not instituted, dissemination can occur in 36% of infected patients, with a mortality rate of 10%.

Hepatitis.

Acute or chronic hepatitis can follow HSCT and has infectious and noninfectious causes (Box 96.5). Hepatitis C virus can infect HSCT recipients, and activation occurs at the time of discontinuation of immunosuppressive therapy.[45]

Box 96.5

Differential Diagnosis of Hepatitis After Hematopoietic Stem Cell Transplantation

Infectious Causes

Hepatitis viruses A, B, C, D, and E

Herpes simplex virus

Cytomegalovirus

Adenovirus

Echovirus

Epstein–Barr virus

Varicella-zoster virus

Human herpesvirus 6

Noninfectious Causes

Veno-occlusive disease

Graft-versus-host disease

Chemotherapy-induced hepatitis

Hepatopathy of total parenteral nutrition

Cholestatic liver injury due to septicemia

Nonchemotherapeutic drugs, including acetaminophen and antibiotics

Laboratory Findings and Diagnosis

Microbiologic evaluation is the gold standard for the diagnosis of infection. Microbiologic tests include blood cultures for bacteria and fungi. Blood cultures should be obtained from each lumen of the central venous line and a peripheral vein.[46] If bacteria or fungi are detected in the blood culture, use of real-time polymerase chain reaction (PCR) can reduce the time to identification of microorganisms and can identify certain antimicrobial resistance genes.[47] When clinically indicated, additional testing includes detection of viral infection by serology, culture, PCR, and immunohistochemical stains on pathologic specimens.

PCR testing is extremely helpful for the screening and diagnosis of viral infections. PCR is available for all the herpesviruses, adenovirus, and polyomaviruses.[11,26,35,48] PCR panels can be used to detect viruses from respiratory specimens, allowing rapid detection of influenza virus, RSV, parainfluenza virus, metapneumovirus, adenovirus, and others.[49,50]

Other laboratory tests are of limited value. The use of the (1-3)-β-D-glucan assay as a screening tool for fungal infection has limited value primarily because several factors can confound the interpretation of the results.[23,46,51] The galactomannan assay is best used longitudinally and only for patients at risk for invasive aspergillosis.[46] A single negative serum test should never be used to rule out invasive fungal infection.[46] Complete blood cell counts can be used to assess engraftment status. An absolute neutrophil count of $<500/\text{mm}^3$ is associated with higher incidence of bacterial infections. Serum hepatic enzyme levels and renal function tests can provide evidence of pathology from an infectious agent or insults from chemotherapy or GvHD (see Boxes 96.2 and 96.5).

Management and Presumptive Therapy

Initial management of patients with fever and neutropenia is similar to management of patients with chemotherapy-induced fever and neutropenia (see Chapter 97). An empiric antibiotic therapy regimen consists of an antipseudomonal β-lactam, cefepime or piperacillin-tazobactam, or carbapenem.[46,51] With rising antimicrobial resistance, every effort should be made to reserve carbapenems for patients with antibiotic allergy or resistant gram-negative infections.

Monotherapy has shown to be noninferior to combination therapy.[46,51] β-Lactam monotherapy avoids the use of aminoglycoside in patients who have received nephrotoxic drugs. Cefepime and piperacillin-tazobactam provide empiric coverage for *Pseudomonas aeruginosa*, other gram-negative, and susceptible gram-positive bacteria. Vancomycin may be added for high-risk patients such as those with severe mucositis, those at risk for infection with methicillin-resistant *Staphylococcus aureus* (MRSA) or other resistant gram-positive bacteria and those with severe sepsis.[46] Vancomycin should be discontinued 2 to 3 days after initiation if no gram-positive resistant bacteria are identified.[46] Choice of antibiotic regimens should take into account isolates indicating the patient's colonization status, the hospital environment, and the antimicrobial resistance pattern within the community and hospital.

For persistently febrile neutropenic patients without an identified bacterial source at 96 or more hours, empiric antifungal therapy should be initiated.[46,51] Lipid or liposomal formulations of amphotericin B, caspofungin, and voriconazole may be used as empiric therapy.[46,51] Liposomal amphotericin B may be less nephrotoxic than amphotericin B deoxycholate.[51] Azole agents such as posaconazole and voriconazole are effective for the treatment of invasive aspergillosis in immunocompromised hosts.[12,52] The echinocandins, caspofungin, and micafungin, alone or in combination therapy with an azole or amphotericin B, are effective for *Candida* spp. infections and invasive aspergillosis.[53–55] Micafungin has been evaluated for salvage therapy for pulmonary aspergillosis, but the dosage has not been established.[12]

Viral infections are treated after a diagnosis is made if therapy is available. Acyclovir is the treatment of choice for HSV and VZV infections. Orally administered valacyclovir and famciclovir also can be used to treat HSV infections. CMV pneumonitis is treated with ganciclovir and immune globulin intravenous (IGIV) to inhibit proliferation of CMV and possibly to abrogate the immune response contributing to the pneumonitis. Foscarnet can be used in cases of ganciclovir-resistant CMV or acyclovir-resistant HSV infections. Cidofovir is used to treat adenovirus and BK virus, and it is used as a second-line agent for herpesvirus infections.[56–59] There are no randomized, controlled trials of pediatric HSCT to demonstrate the efficacy of treatment of adenovirus infection.[56] In a nonrandomized, single-dose pilot study, cidofovir was well tolerated by most children, and the pharmacokinetics, other than a longer drug half-life, were similar to published adult data.[56]

Adoptive immunotherapy, by transferring virus-specific cytotoxic T lymphocytes to patients after allogeneic HSCT, has been used to treat infections caused by EBV and CMV.[60] It also is used selectively to reconstitute immune function against these viruses.[61]

For respiratory viral infections, pre-emptive aerosolized ribavirin for upper respiratory RSV infection appears to be safe and may decrease the RSV nasal viral load.[62] Ribavirin has not been proved efficacious for the treatment of parainfluenza virus infection.[63] Current evidence does not support the therapeutic use of palivizumab, an RSV-specific monoclonal antibody, because it may not prevent RSV progression to lower respiratory tract disease.[64] Limited data are available for the treatment of human metapneumovirus infection.[63] The use of neuraminidase inhibitors should be considered for patients with influenza infection, even if initiation of therapy is delayed, because a beneficial effect still may be observed.[63]

Prevention

Prevention of infectious complications is a high priority for recipients of HSCT. Prophylaxis against PCP using TMP-SMX is started after engraftment and is given orally three times per week until 6 months after transplantation. The dose is 5 to 10 mg/kg/day divided into 2 doses or 150 mg/m^2/day divided into 2 doses for 3 consecutive days per week.

For HSCT recipients with neutropenia, fluconazole, posaconazole, or micafungin is recommended during the period of risk of neutropenia for prophylaxis against candidiasis.[55,65] However, the use of fluconazole has been complicated by the emergence of resistant pathogens such as *Candida krusei* and other *Candida* species.[20] Antifungal prophylaxis using posaconazole can be recommended for HSCT recipients with GvHD who are at high risk for invasive aspergillosis.[12]

The risk of primary CMV infection can be decreased for the CMV-seronegative HSCT recipient by using leukocyte-filtered blood products for transfusion. Since the introduction of prophylaxis with ganciclovir for CMV infection, the incidence of CMV disease has been reduced substantially.[30] Pre-emptive therapy with ganciclovir or foscarnet is used in seropositive HSCT recipients or in patients receiving a transplant from a seropositive donor. The use of ganciclovir as prophylaxis can cause neutropenia, which increases the risk of a bacterial infection, but the risk of CMV pneumonia justifies its use. Pre-emptive ganciclovir therapy administered early in the course of HSCT delays the median time of onset of CMV infection from 1 to 2 months to 4 to 6 months, when immune reconstitution is more advanced.[66]

Active Immunizations

Reimmunization is important because most allogeneic and a large proportion of autologous recipients of HSCT lose their immunity to vaccine-preventable diseases. When reimmunizing transplant recipients, recent administration of immunoglobulin preparations (except monoclonal antibody to RSV) must be considered because of interference with the response to live virus vaccine (i.e., measles, mumps, rubella, and varicella).

Immunization can be started 3 months after HSCT. One schema (Table 96.2) is based on the Infectious Diseases Society of America (IDSA) guidelines for vaccination of the immunocompromised host.[67] Inactivated influenza vaccine should be administered annually in early autumn to recipients of HSCT beginning 6 months after transplantation. For people who are less than 6 months after HSCT during the influenza season, chemoprophylaxis should be considered. The live attenuated influenza vaccine should not be administered to HSCT recipients.[6,67–71] Vaccination of the donor for the benefit of the recipient is not recommended.[67] Inactivated vaccines pose no risk to HSCT recipients. Live vaccines should not be administered to HSCT patients with active GvHD or ongoing immunosuppression.[67,69]

TABLE 96.2

Immunization Schedule for Hematopoietic Stem Cell Transplant Recipients

Months After Transplantation	Vaccines
3–6	Pneumococcal[a]
6–12	DTaP,[b,c] IPV[c], Hib[c], meningococcal,[d] hepatitis A[e] and B[c], HPV[c,f]
24	MMR,[g] varicella

[a] Three doses of 13-valent conjugate vaccine should be given between 3 to 6 months post-HSCT followed by a dose of 23-valent pneumococcal vaccine at 12 months after hematopoietic stem cell transplantation (see Chapters 6 and 123).

[b] For patients ≥7 years of age, a dose of Tdap should replace DTaP, and it should be followed by 2 doses of TD or Td vaccine.

[c] Three doses between 6 to 12 months after transplantation.

[d] Two doses of meningococcal conjugate vaccine if indicated by age.

[e] Consider for patients who have chronic liver disease or chronic GvHD or those who live in areas with endemic infection.

[f] For patients between 11 and 26 years of age.

[g] Two-dose series starting 24 months after hematopoietic stem cell transplantation. Do not use live virus vaccines in patients with chronic GvHD or those receiving corticosteroid therapy.

DTaP, Diphtheria and tetanus toxoids and acellular pertussis; GvHD, graft-versus-host disease; Hib, *Haemophilus influenzae* type B; IPV, poliovirus vaccine inactivated; MMR, measles, mumps, rubella; Tdap, diphtheria, tetanus toxoid, acellular pertussis vaccine; HPV, human papillomavirus vaccine.

Passive Immunization and Immunoglobulin Use

Because of its antimicrobial and immunomodulatory effect, IGIV has been administered to HSCT recipients with no advantage in terms of survival or infection prevention.[72] The indications for passive immunization with specific immune globulin preparations (e.g., hepatitis B, tetanus, rabies) in patients after HSCT are similar to those in otherwise healthy people. Passive immunization is recommended for susceptible people with known exposure to varicella (see Chapter 205).

Key Points

Infections in Hematopoietic Stem Cell Transplantation Recipients

Epidemiology and Etiologic Agents

- Immune deficiencies after HSCT in the phagocytic, humoral, and cellular arms of the immune system cause susceptibility to infectious agents in three distinct periods.

- Most infections are derived from the patient's microbial flora or reactivation of a latent infection.

- ▪ Allogeneic HSCT recipients are at higher risk for infection than autologous HSCT recipients.

Clinical Syndromes, Differential Diagnosis, and Clinical Approach

- Approach according to the risk period after transplantation

- ▪ Early period (i.e., before engraftment): HSV, CLABSI, and fungal infection

- ▪ Middle period (i.e., early engraftment): CLABSI, adenovirus, CMV, pneumonitis, and toxoplasmosis

- ▪ Late period: CLABSI, VZV, and hepatitis

Laboratory Findings and Diagnosis

- Microbiologic testing is the gold standard for diagnosis.

- PCR testing is helpful for screening and confirmation of viral infections.

Management and Presumptive Therapy

- Manage HSCT patients as for febrile neutropenic patients with cancer.

- Begin antifungal therapy if fever continues ≥96 hours after commencement of antibiotic therapy.

- Begin antiviral treatment when the diagnosis is made.

Prevention

- Antimicrobial prophylaxis is important to prevent certain infections (e.g., PCP, CMV).

- Reimmunization is important because most recipients of HSCT lose prior immunity to vaccine-preventable diseases.

CLABSI, Central line–associated bloodstream infection; CMV, cytomegalovirus; HSCT, hematopoietic stem cell transplantation; HSV, herpes simplex virus; PCP, *Pneumocystis* pneumonia; PCR, polymerase chain reaction; VZV, varicella-zoster virus.

Infections and Cancer

OUTLINE

97 Fever and Granulocytopenia
98 Infections in Children With Cancer

97

Fever and Granulocytopenia

Monica I. Ardura, Andrew Y. Koh

Infection remains a major cause of morbidity in children with cancer. Fever and neutropenia are among the most common complications of cancer therapy in children. The use of empiric antimicrobial regimens in this patient population began with the observation that febrile neutropenic patients with cancer who had potentially fatal infections could not be distinguished from patients who had less serious or noninfectious illnesses and has since led to a reduction in infection-related morbidity and mortality rates.

Epidemiology and Outcome

Fever may be the first or only manifestation of an infection in a neutropenic patient. Studies completed in the late 1970s suggested that more than one half of children with fever and neutropenia had a clinically or microbiologically proven infection, with a causative agent documented in almost two thirds of infectious episodes.[1] More recent data demonstrate that the incidence of microbiologically proven infection in febrile and neutropenic children is lower and that bloodstream infection (BSI) is the most frequently documented infection. (10%–40%)[2–7] In several large series published in the 1990s, the mortality rates for febrile and neutropenic patients ranged from 1% to 19%.[8–13] Fever without documented cause now accounts for approximately two thirds of febrile episodes, perhaps because of earlier use of empiric antibiotic therapy. Neutropenic patients can have serious infections in the absence of fever. Therefore, neutropenic patients who develop signs or symptoms suggestive of a localized infection should be managed according to the same principles as neutropenic patients who present with fever. The same is true for afebrile neutropenic patients with hypothermia, hemodynamic instability, or localized pain despite the lack of erythema, purulence, or swelling because signs of an inflammatory response may be attenuated in the setting of severe neutropenia.

Children with cancer differ from their adult counterparts in several ways. Febrile children often do not have a clinically apparent site of infection. When a clinically apparent site is present, children are more likely than adults to have upper respiratory tract findings. Whereas the incidence of BSI is similar in children and adults, the rate of death during fever and neutropenia is 1% in children compared with 4% in adults.[8]

Pathogenesis and Etiologic Factors

The interactions of complex factors in cancer and its treatment lead to the high risk for serious infection in patients undergoing cancer treatment (see Tables 97.1 to 97.4).

TABLE 97.1

Predominant Pathogens Infecting Children With Anatomic Disruptions

Site	Bacteria	Fungi	Other
Oral cavity	α-Hemolytic streptococci Oral anaerobes	*Candida* spp.	Herpes simplex virus
Esophagus	Staphylococci Other colonizing organisms	*Candida* spp.	Herpes simplex virus Cytomegalovirus
Lower gastrointestinal tract	Gram-positive: group D streptococci Gram-negative: enteric organisms Anaerobes: *Bacteroides fragilis*, *Clostridium perfringens*	*Candida* spp.	Cytomegalovirus *Strongyloides stercoralis*
Skin (intravenous catheter)	Gram-positive: staphylococci, streptococci, corynebacteria, *Bacillus* spp.	*Candida* spp. *Aspergillus* spp. *Malassezia furfur*	

	Gram-negative: *Pseudomonas aeruginosa*, enteric organisms		
Urinary tract	Gram-positive: group D streptococci Gram-negative: enteric organisms, *P. aeruginosa*	*Candida* spp.	

TABLE 97.2

Predominant Pathogens Infecting Children With Neutropenia

Category	Organisms
Bacteria	Gram-negative enteric organisms: *Escherichia coli, Klebsiella pneumoniae, Enterobacter* spp., *Citrobacter* spp., *Pseudomonas aeruginosa, Bacteroides* spp.
	Gram-positive: Staphylococci: coagulase-negative, coagulase-positive Streptococci: group D, α-hemolytic, anaerobic Clostridia
Fungi	*Candida* spp. *(C. albicans, C. tropicalis, other species)*
	Aspergillus spp. *(A. fumigatus, A. flavus)*

TABLE 97.3

Predominant Pathogens Infecting Children With Defects in Cell-Mediated Immunity

Bacteria	Fungi	Viruses	Other
Legionella	*Cryptococcus neoformans*	Varicella-zoster virus	*Toxoplasma gondii*
Nocardia asteroides	*Histoplasma capsulatum*	Herpes simplex virus	*Cryptosporidium*
Salmonella spp.	*Coccidioides immitis*	Cytomegalovirus	*Strongyloides stercoralis*
Mycobacteria	*Candida* spp.	Epstein-Barr virus	
Mycobacterium tuberculosis and nontuberculous mycobacteria	*Pneumocystis jirovecii*	Hepatitis B	
Disseminated bacille Calmette-Guérin			Disseminated infection from live virus vaccines (vaccinia, measles, rubella, mumps, yellow fever, or poliovirus)

TABLE 97.4

Predominant Pathogens Infecting Children With Defects in Immunoglobulins, Complement, and Splenic Function[a]

Defect	Organisms
Immunoglobulin abnormalities	Gram-positive:

	Streptococcus pneumoniae
	Staphylococcus aureus
	Gram-negative:
	Haemophilus influenzae
	Neisseria spp.
	Enteric organisms
	Viruses: enteroviruses (including polioviruses)
	Protozoa: *Giardia lamblia*

Anatomic Disruptions and Devices

Alteration of skin or mucosal integrity or obstruction of an organ or body cavity predisposes to infection (Table 97.1). Cytotoxic chemotherapy damages oral and gastrointestinal tract mucosa while concomitantly inducing neutropenia. Devices that violate skin integrity, such as central venous catheters (CVCs) and peripherally inserted central catheters, also significantly increase (~40-fold) the risk of infection.[14,15] Depending on the specific patient population, techniques of catheter insertion and care, treatment regimens, and the definition of CVC-related infections, infections occur in 9% to 80% of patients.[16,17]

Some studies have suggested that the incidence of infection is lower for patients with totally implanted devices (e.g., Port-A-Cath, Smiths Medical, Dublin, Ohio) compared with patients with external, tunneled CVCs (Hickman-Broviac–type catheters).[18–20] A prospective, randomized study, however, failed to demonstrate a difference in rates of infection.[21] The use of a central catheter for delivery of parenteral nutrition increases the risk of infection by ~2.4 fold, independent of the type of catheter used.[22] A systematic review of published studies concluded that all types of intravascular catheters pose a risk for local and catheter-associated BSI and that appropriate guidelines for prevention of catheter-related infections, from insertion to maintenance, should be followed.[23,24]

Devices other than CVCs also have been associated with an increased risk of infection in immunocompromised patients. Limb-sparing procedures for patients with osteosarcoma use prosthetic bone and joint hardware that has been associated with high rate of infections.[25] In some institutions, children with such prosthetic devices are not considered candidates for permanent CVCs because of the higher risk of BSI and seeding of the prosthesis. The relative risk of infection in children with limb prostheses is not known, and optimal management has not been defined. With any device, the importance of microbial biofilm formation and the mechanisms by which these organisms may perpetuate seeding of the bloodstream and promote emergence of antibiotic resistance cannot be overemphasized.[26,27]

Neutropenia

The most important risk factor in the development of infections in children with cancer is neutropenia resulting from cytotoxic chemotherapy. The relationship between neutrophil numbers and the risk of infectious complications in patients with leukemia was first described in 1966 by Bodey and colleagues[28] at the National Cancer Institute. The investigators concluded the following: (1) the risk of infection was inversely related to the absolute neutrophil count (ANC), with infections being more prevalent when the ANC fell to less than 1000 cells/mm^3 and increasing in likelihood and severity with ANC <500 cells/mm^3 and further with ANC ≤100 cells/mm^3; (2) relapse of leukemia was associated with higher rates of infection than remission at all levels of neutrophil count; and (3) the duration of neutropenia was the single most important factor in predicting risk of infection. Severe neutropenia that lasted longer than 3 weeks was associated with a 100% risk of infection and the highest mortality rates.[28] These observations were confirmed over ensuing years and led to the current approach to management of patients with fever and neutropenia.[29–31] Organisms causing infections in children with neutropenia are listed in Table 97.2.

Normal Microbiota

Commensal microbes stimulate the gastrointestinal epithelium to produce antimicrobial peptides (AMPs) that act as a first line of defense against invading pathogenic bacteria.[32] When indigenous commensals are depleted after antibiotic administration, select pathogenic bacteria (e.g., vancomycin-resistant enterococci [VRE]) can overgrow and cause invasive disease.[33] Stimulating intestinal toll-like receptor 4 (TLR4) by oral administration of lipopolysaccharide,[33] or stimulating TLR5 with purified flagellin,[34] reinduces AMP RegIIIγ and results in a decrease of VRE in the gastrointestinal tract. Thus, methods for maintaining microbial homeostasis during chemotherapy and antibiotic therapies may provide a novel means for preventing colonization and dissemination of pathogenic microbes.

Other Defects

Repeated cycles of cytotoxic therapy not only decrease circulating neutrophils but also deplete lymphocytes and natural killer cells.[35] Reduced lymphocyte subset populations were associated with opportunistic infections in a group of patients receiving dose-intensive chemotherapeutic regimens.[35] Because TLRs are key components of innate host response, responsible for recognition of pathogens and cytokine response to surface molecules,[36,37] it is not surprising that an association exists between donor TLR4 haplotype and the risk of invasive aspergillosis.[38] Similarly, other TLR4 single nucleotide polymorphisms have been associated with susceptibility to infections caused by gram-negative bacteria,[39] *Candida albicans*,[40] and respiratory syncytial virus.[41] Organisms causing infections in children that are related to defects in cell-mediated immunity are listed in Table 97.3, and organisms related to immunoglobulin and complement abnormalities, as well as splenic dysfunction (or absence), are listed in Table 97.4.

Etiologic Agents

Infections in immunocompromised children can result from bacteria, fungi, viruses, or protozoa. Changes in the epidemiology of these infections in the neutropenic host are multifactorial, including fluctuations in antimicrobial practices, increased use of indwelling devices, more intensive chemotherapy regimens, evolving infection control measures, and emergence of resistant organisms.

Bacteria

Infections in immunocompromised children can result from organisms from the host's endogenous bacterial flora. With hospitalization and antibiotic therapy (including antineoplastic chemotherapy), a shift in normal flora occurs to include potentially pathogenic gram-negative bacteria.[42] Underlying disease and exposure to broad-spectrum antibiotics likely contribute to changes in microbial populations.[43] Approximately one half of pathogens responsible for documented infections are acquired by oncology patients after initial admission to the hospital,[44] including antibiotic-resistant gram-positive and gram-negative organisms.

The relative incidence of gram-negative infections has decreased since the early 1980s, whereas the incidence of gram-positive infections in this population has risen.[8,45] Currently, gram-positive organisms, particularly coagulase-negative staphylococci, *Staphylococcus aureus* (and especially methicillin-resistant *S. aureus* [MRSA]), α-hemolytic streptococci, enterococci, and *Corynebacterium* spp., account for more than one half of documented infections in patients with cancer. *Escherichia coli, Pseudomonas* species, and the *Enterobacter-Klebsiella-Serratia* group are identified in a smaller but significant proportion of patients.[8,45–47]

Although BSI with gram-positive organisms generally is associated with lower mortality rates than is BSI associated with gram-negative organisms, the syndrome of α-hemolytic streptococcal septicemia deserves special attention.[48] The α-hemolytic streptococci (viridans group streptococci) are normal inhabitants of the oral cavity and the gastrointestinal and respiratory tracts.[49] Neutropenic patients with acute myeloid leukemia, those receiving cytosine arabinoside, and hematopoietic stem cell transplant (HSCT) recipients are at highest risk of viridans streptococcal sepsis syndrome.[50,51] *Streptococcus mitis* and *Streptococcus sanguis* are the most commonly associated α-hemolytic streptococci. Septic shock and respiratory distress can progress rapidly to death; mortality rates range from 10% to 100%.[52,53] Fever often persists despite sterilization of blood, and patients can progress to shock after 48 to 72 hours despite clearance of BSI. Secondary myositis and even myocarditis rarely have been reported with α-hemolytic streptococcal BSI.[54,55] Penicillin resistance is not uncommon among these previously susceptible organisms.[47,56] Increased use of systemic antibiotics for treatment and prophylaxis (especially with fluoroquinolones and trimethoprim-sulfamethoxazole) has led to an increase in penicillin-resistant α-hemolytic streptococci. It is important to know local antibiotic resistance patterns and to request antimicrobial susceptibility testing on all clinically relevant isolates.

Widespread use of vancomycin has been linked with increasingly vancomycin-resistant *Enterococcus* spp. and *Staphylococcus* spp.[57,58] Community-acquired MRSA (CA-MRSA) is an important cause of invasive infections including sepsis,[59] necrotizing fasciitis,[60] and pneumonia[61] in adults and children without recognized risk factors.[62,63] *S. aureus* can cause serious infections in pediatric oncology patients.[64,65] Increasing prevalence of CA-MRSA nasal and rectal colonization was described in children at a large US pediatric cancer center; patients colonized with Panton-Valentine leukocidin–positive strains are more likely to develop infection and recurring infection. Although CA-MRSA isolates are likely to be susceptible to non–β-lactam antibiotics (such as clindamycin, trimethoprim-sulfamethoxazole, and rifampin), macrolide-lincosamide-streptogramin resistance and constitutive and inducible resistance to clindamycin have occurred at variable prevalence geographically.[63,66]

Infections resulting from gram-negative bacilli, particularly *Pseudomonas aeruginosa* BSI, continue to carry high mortality rates.[67] Therefore, although these infections have become less frequent than gram-positive infections, empiric antimicrobial coverage, especially for *P. aeruginosa,* remains important in children with fever and neutropenia. Increasing antibiotic resistance of gram-negative organisms to β-lactam agents (e.g., extended-spectrum penicillins and cephalosporins) and to carbapenems, aminoglycosides, and quinolones has been observed.[68] Of particular concern are *Enterobacter* and *Serratia* spp., which are prone to rapid development of resistance caused by inducible β-lactamases.

Infections with anaerobic organisms occur infrequently in febrile, neutropenic patients despite the predominance of these organisms in the normal gut microbiota. Nonetheless, anaerobic infections, often polymicrobial, can cause BSI (<5%) with associated high mortality rates.[69,70] The most commonly isolated anaerobic organisms are *Bacteroides* spp. and *Clostridium* spp.,[71,72] which have been associated with specific syndromes, such as peritonitis, abdominal or pelvic abscesses, and perirectal cellulitis.[73,74] Anaerobes also contribute to infections of the oral cavity, especially necrotizing gingivitis. *Clostridium perfringens and Clostridium septicum* can cause a devastating infection characterized by septic shock and rapidly progressive necrotizing fasciitis with myonecrosis. Infection may arise from a traumatic or surgical wound or spontaneously from an abdominal source, such as necrotic bowel. Pseudomembranous colitis caused by toxins of *Clostridium difficile* can result in a wide spectrum of clinical manifestations, from mild diarrhea and cramping to toxic megacolon and intestinal perforation. *Fusobacterium* spp. BSI has been associated with severe mucositis and fluoroquinolone prophylaxis.[75] The possibility of an anaerobic infection should be considered in neutropenic patients with severe mucositis, abdominal or perirectal symptoms, or necrotic skin lesions or in patients who remain hemodynamically unstable despite broad antibiotic therapy that does not cover anaerobic bacteria (e.g., cefepime).

Fungi

With improved treatment and better survival from bacterial infections in febrile neutropenic patients, prevention and treatment of fungal infections have great importance, especially in patients with prolonged neutropenia. In the 1980s, investigators noted that prolonged or relapsing fever that occurred during ≥7 days of antibiotic therapy for fever and neutropenia was associated with invasive fungal infections and that empiric antifungal therapy improved outcomes.[76] Fungi are rarely the cause of the initial episode of fever and neutropenia.[2,77]

Historically, *C. albicans* was the most common species isolated. It accounted for approximately 50% of isolates, with non-*albicans Candida* species (e.g., *Candida tropicalis, Candida parapsilosis, Candida krusei*, and *Candida glabrata*) making up the remaining one half of isolates.[78–80] More recent prospective pediatric studies demonstrated the emergence of non-*albicans Candida* species causing invasive disease.[81] This changing pattern may reflect, in part, the use of oral antifungal agents prophylactically, as well as factors related to the host and fungal species.[82–84]

Aspergillus spp. are the second most common causes of invasive fungal infections in neutropenic patients in most hospitals. *Aspergillus fumigatus* and *Aspergillus flavus* are the species most frequently isolated. Other fungi that cause serious infection in neutropenic children are *Mucor, Fusarium, Trichosporon* spp., and the Phaeohyphomyces (also known as dematiaceous molds including *Curvularia, Bipolaris, Alternaria*, and *Exserohilum*). These organisms are not part of the normal flora of the respiratory or gastrointestinal tract, but after colonization, they can become invasive when chemotherapy renders the host susceptible. These molds are ubiquitous in the environment; temporal relationships between construction and an increase in invasive mold infection in neutropenic patients have been described.[85–88] Infection with yeasts such as *Histoplasma, Cryptococcus*, and *Coccidioides* are more commonly associated with defects of cell-mediated immunity, but they can occur in neutropenic patients as primary infections or reactivated disease.

Pneumocystis jirovecii (formerly *Pneumocystis carinii*) is a major fungal pathogen in children with cancer.[89] In patients with cancer, *P. jirovecii* infection generally is caused by reactivation of latent organisms. It appears to be associated with more rapidly progressive pneumonia than that seen in adults and older children infected with human immunodeficiency virus (HIV).[90,91] The risk of *Pneumocystis* pneumonia (PCP) and the severity of disease are related to the underlying malignant disease, the intensity of immunosuppressive regimens including corticosteroids (a feature that explains particular occurrence in children with leukemia, lymphomas, and brain tumors), and the use of prophylaxis. Symptomatic disease has been strongly associated with tapering and discontinuation of corticosteroids.[91–93] The possibility of PCP should be considered in children with cancer who have diffuse pulmonary infiltrates and hypoxemia. Confirmation of the diagnosis requires detection in respiratory specimens by using traditional microscopy with staining demonstrating cysts or trophozoites in sputum or bronchoalveolar lavage specimens. The use of PCP polymerase chain reaction and (1,3)-β-D glucan assays on respiratory fluid samples has improved diagnostic yields in patients with hematologic malignant diseases.

Viruses

Herpes simplex virus and varicella-zoster virus were identified as the most common viral pathogens in a prospective study of children with leukemia.[94] The incidence of viral infections is higher in children undergoing induction or during relapse than during remission.[95] Other viruses, including influenza virus, parainfluenza virus, cytomegalovirus, human herpesviruses 6 and 8, adenovirus, measles virus, respiratory syncytial virus, and enteroviruses, also can lead to substantial morbidity. Although some viral illnesses (e.g., dermatomal zoster or herpetic stomatitis) cause clinically recognizable lesions that are easily confirmable, others illnesses have nonspecific symptoms or localize to areas that are less accessible (e.g., cytomegalovirus hepatitis or viral encephalitis). Common respiratory tract viruses can cause lower respiratory tract infection. Respiratory viral infection has been documented in 34% to 57% of febrile, neutropenic patients.[3,96,97]

Parasites

Parasites such as *Toxoplasma gondii* and *Cryptosporidium* rarely occur in children with cancer, but they can be associated with significant morbidity. *T. gondii* can cause fulminant disseminated disease but most often is localized to the central nervous system. Stem cell transplant recipients are at the highest risk of developing toxoplasmosis of the central nervous system.[98] *Cryptosporidium* should always be considered in any pediatric patient with cancer who has severe or prolonged diarrhea.[99]

Differential Diagnosis and Clinical Approach to Diagnosis

Many oncology centers have adopted a standardized approach to the evaluation of febrile, neutropenic patients to ensure that all potentially dangerous causes of fever are considered (Box 97.1). *Neutropenia* is defined as an existing ANC of fewer than 500 neutrophils/mm^3 or ANC <1000 neutrophils/mm^3 and expected decrease to <500 neutrophils/mm^3 in the subsequent 48 hours. Severe or profound neutropenia describes an ANC <100 cell/mm^3. *Fever* is defined as a single oral-equivalent temperature of at least 38.3°C (101°F), or a temperature recorded that is higher than 38.0°C (100.4°F) sustained over a 1-hour period. Documentation of fever by the patient or caretaker should always be accepted, even if the child is afebrile at the time of medical evaluation. Some life-threatening infections can occur in the absence of fever in profoundly neutropenic patients with localizing signs or symptoms (e.g., right lower quadrant abdominal pain).[100]

Box 97.1

Initial Diagnostic Evaluation of Children With Fever and Neutropenia

Careful medical history

Physical examination (which should be repeated at least daily in febrile neutropenic patients) with attention to the skin, perirectal area, and other mucosal sites

Specimens for diagnostic evaluation:

- Blood: specimens from every lumen or accessed port of intravascular catheters for blood culture; consideration of specimen from a peripheral site
- Urine for culture

- Respiratory secretions: for bacteria and viruses if symptoms are present
- Any site with clinical signs of infection, including bacterial or fungal cultures from skin sites, *Clostridium difficile* toxin assay if diarrhea present

Chest imaging if lower respiratory tract symptoms

- Other imaging studies or diagnostic procedures as clinically indicated
- Sinus radiograph or computed tomography
- Abdominal ultrasonography or computed tomography

The diagnostic evaluation of the child with fever and neutropenia should be guided by clinical history and physical examination findings. A history of possible infectious exposures should be sought, and careful physical examination should be repeated frequently throughout the period of observation and empiric treatment. Unfortunately, such examinations identify a potential site of serious infection in a minority of patients. The traditional markers of inflammation can be muted or even absent in children who lack neutrophils, and thus the usual manifestations of serious infection, such as chills, rigors, and "toxic appearance," may not help distinguish patients with BSI or other serious infection. Examination of the oral and nasal cavity, perirectal area, and skin (including the CVC site) must not be overlooked.[2,13]

Specimens for culture from suggestive sites should be obtained. Blood cultures should be obtained from each lumen of the CVC before institution of antibiotic therapy. The utility of concomitant blood cultures from a peripheral site is controversial. Peripheral cultures may be useful in diagnosing CVC-associated BSI and aiding in CVC management (e.g., salvage versus removal).[101] The proportion of true BSI detected by peripheral blood cultures when CVC cultures were negative was 13% (95% confidence interval, 8% to 18%) in one study.[31] Optimal blood culture volume should always be obtained to ensure an adequate diagnostic yield. Because urinary tract infections are among the most prevalent infections (with frequencies of 8.6% during fever and neutropenia episodes) and can be subclinical, urine should be obtained for culture from all patients. Pyuria can be absent in children with neutropenia.[13,102] During seasonal outbreaks of viral infection of the respiratory tract, a throat or nasopharyngeal specimen should be obtained for viral antigen or polymerase chain reaction testing. Pulmonary imaging should be considered at the time of initial evaluation of fever and neutropenia in patients with lower respiratory tract symptoms; the yield in asymptomatic neutropenic patients is small.[103,104] Pulmonary infiltrates not present initially may become apparent with bone marrow recovery, when neutrophils are recruited to a site of previously "silent" infection.

The value of surveillance cultures in patients undergoing chemotherapy has been studied. In a survey of 652 episodes of fever and neutropenia in which surveillance cultures of nose, throat, urine, and stool were performed, 62% of patients who developed BSI had been colonized with the infecting organism. However, management of these patients was not substantially influenced by this information because multiple potential pathogens often were isolated from the same site. No single site was predictive of BSI, and the blood isolate frequently was identified before results of surveillance cultures were available.[105]

Management and Empiric Therapy

An empiric antibiotic regimen for febrile neutropenic episodes should: (1) provide a broad spectrum of activity against a variety of pathogenic organisms, including but not limited to *Pseudomonas*; (2) be bactericidal; and (3) have low potential for adverse effects or emergence of resistant organisms. Because large randomized controlled trials to determine the optimal management of children with fever and neutropenia are lacking, recommendations mainly are derived from studies conducted in adults, consensus guidelines, and historical data.

Empiric Therapeutic Regimens

Empiric, broad-spectrum antibiotic therapy continues to be the standard of care for patients with fever and neutropenia. Numerous regimens have been evaluated over the last several decades, with most large comparative clinical efficacy trials including both adults and children. No single empiric regimen has demonstrable superiority; many of the regimens studied are similar in efficacy, although study designs and definitions of success have not been uniform. Evidence-based clinical practice guidelines are published[30,31]; however, the choice of a specific agent or combination should be based on multiple factors including the patient's clinical presentation (severity, manifestation, risk factors), previous history of infection or colonization with resistant organisms, prophylactic antimicrobial regimens, and specific patterns of infection and susceptibility profiles in one's own institution.

Historically, empiric regimens consisted of 2 agents with antipseudomonal activity. Monotherapy was pioneered by the National Cancer Institute to simplify antibiotic regimens and reduce toxicity in children who often receive complex chemotherapeutic regimens. Monotherapy with ceftazidime had equivalent efficacy (i.e., survival of patients with fever and neutropenia) compared with combination regimens regardless of whether a site of infection could be documented. However, many patients required modifications of the initial regimen if they had a documented site of infection or >7 days of neutropenia. Additional studies evaluating cephalosporins (e.g., cefepime[106–108]), as well as carbapenems,[9,109,110–112] as single agents for fever and neutropenia showed comparable efficacy and provided options for management. In both adults and children, monotherapy with an antipseudomonal antibiotic was found to be as effective as combination regimens and was associated with fewer toxicities.[113,114] Furthermore, no differences were reported in treatment failures, adverse events, or mortality rates when comparing monotherapy with antipseudomonal penicillins versus antipseudomonal cephalosporins or carbapenems. Ceftazidime may no longer be a reliable agent in many centers because of increasing resistance of gram-negative bacteria and poor coverage against gram-positive pathogens. Piperacillin-tazobactam, cefepime, or meropenem is used for first-line empiric monotherapy in high-risk neutropenic patients with fever who are otherwise stable.[30,31] A patient's clinical syndrome should further guide antibiotic choice (e.g., to use piperacillin-tazobactam or meropenem compared with cefepime for suspected intra-abdominal infection).

In patients who are clinically unstable, initiation of additional empiric antibiotics is prudent pending results of cultures and clinical progression. Routine use of vancomycin as part of the empiric antimicrobial regimen in patients with fever and neutropenia is not recommended. Results from randomized trials concluded that empiric use of vancomycin did not improve treatment success, shorten duration of fever, or improve mortality rates, and it was associated with significantly more adverse events, including nephrotoxicity.[115,116] Vancomycin should be chosen empirically for patients with higher likelihood of gram-positive infections, including patients who have hemodynamic instability, evidence of skin or soft tissue infection or catheter-associated pocket or tunnel infection, lobar pneumonia, or a history of previous infection or colonization with MRSA. Another indication for the addition of vancomycin is for patients with severe mucositis who have been receiving fluoroquinolone prophylaxis.[30] The addition of a second antibiotic with activity against gram-negative bacteria should be considered in patients who are clinically unstable or if antimicrobial resistance is suspected (e.g., history of previous colonization with multidrug-resistant gram-negative bacteria). A meta-analysis of randomized controlled trials comparing ciprofloxacin plus β-lactam with aminoglycoside plus β-lactam combinations for the empiric treatment of febrile neutropenia showed comparable or better outcomes with the ciprofloxacin plus β-lactam combination. The authors of this analysis suggested that this combination should be considered only for patients who have not received a fluoroquinolone for prevention of infections and in settings in which fluoroquinolone resistance is not common.[117]

Duration and Modification of Therapy

Modifications of initial empiric antimicrobial therapy should be guided by clinical evolution and microbiologic data. Continued fever alone in an asymptomatic and clinically stable patient without an identified focus of infection does not warrant the addition of antibiotics to the empiric regimen. Conversely, patients who remain hemodynamically unstable after initial empiric antibiotics should have antibiotic coverage broadened to provide additional gram-negative, gram-positive, anaerobic, and fungal coverage. Even when a bacterial pathogen is isolated from a febrile, neutropenic child, evidence supports the continuation of broad-spectrum antibiotic therapy.[118] Obtaining tissue may be necessary for both diagnosis and optimal antimicrobial therapy when fever and neutropenia persist, radiographic imaging is abnormal, and no corroborative microbiologic confirmation occurs. Specific clinical events that may require modification of the initial treatment regimen are described in Chapter 98; recommendations are summarized in Table 97.5.

TABLE 97.5

Modifications of Antimicrobial Therapy During Fever and Neutropenia

Clinical Event	Possible Modifications in Therapy
Breakthrough bacteremia on empiric regimen	If gram-positive isolate, add vancomycin or other gram- positive agent in patient with known history of VRE
	If gram-negative isolate (presumably resistant), change regimen and consider addition of second gram-negative agent
Catheter-associated soft tissue infection	Add vancomycin
Severe oral mucositis or necrotizing gingivitis	Add agent active against β-lactamase–producing anaerobic bacteria; consider acyclovir
Esophagitis	Clotrimazole, ketoconazole, fluconazole, voriconazole, caspofungin, or amphotericin B; consider acyclovir
Diffuse or interstitial pneumonitis	Trimethoprim-sulfamethoxazole; macrolide
New infiltrate in neutropenic patient receiving antibiotics	If neutrophil count rising, can observe If neutrophil count not recovering or has been severe and prolonged, pursue further diagnostics, including possible biopsy; if biopsy not possible, consider agent active against molds
Perianal cellulitis	Add agent active against β-lactamase–producing anaerobic bacteria if not already included in broad-spectrum therapy
Prolonged fever and neutropenia	After 1 week of antibiotics, add antifungal agent

VRE, vancomycin-resistant enterococci.

The duration of antibiotic therapy depends on several factors, including isolation of the presumed pathogen, clinical identification of a presumed infectious process, duration of fever and neutropenia, and the patient's schedule of chemotherapy. Patients who had additional antibiotics (e.g., vancomycin and a second gram-negative agent) added to their empiric regimen, who remain clinically stable without a clinical focus of infection, and whose culture results are negative at 48 to 72 hours can have the additional antibiotics discontinued. If the preantibiotic blood and catheter culture results are negative and no site of infection is determined, the additional gram-positive and gram-negative specific antibiotics may be discontinued, and monotherapy with an antipseudomonal antibiotic may be continued evidence of resolution of neutropenia is noted. If the culture results are positive, a therapeutic course is warranted.

Traditionally, empiric therapy is continued until the ANC has returned to >500 cells/mm^3 and the patient is afebrile.[30] For patients whose infection has been documented (either microbiologically or clinically) and whose resolution of fever and neutropenia has been prompt, the course of antibiotic treatment should be appropriate for the infection identified. Parenteral antibiotics are preferred for patients with serious infections. For patients without a defined site of infection who show signs of bone marrow recovery, antibiotics usually can be discontinued, even before the ANC reaches 500/mm^3. The optimal duration of antibiotic therapy in high-risk patients without a clinical or microbiologic focus of infection who remain profoundly neutropenic is unknown.

Empiric Antifungal Therapy

Patients at high risk for invasive fungal infections include those with acute myeloid leukemia, patients with relapsed acute lymphoblastic leukemia, those receiving intensive myelosuppressive chemotherapy, and HSCT recipients. Additive risk factors include persistent fever despite prolonged broad-spectrum antibiotics and severe or prolonged neutropenia. Fungi have emerged as important causes of infections in patients with prolonged neutropenia by affecting 9% to 31% of this population.[76,119]

Historically, amphotericin B was the only available systemic antifungal agent available. Its use in empiric regimens for prolonged or recurrent fever in neutropenic patients reduced the incidence of documented fungal infections and attributable mortality rates.[76] As a result, antifungal therapy became standard of care, and current guidelines recommend the use of empiric antifungal agents in high-risk patients with no identified fever source whose fever persists or recurs despite 4 to 7 days of broad-spectrum antibiotic therapy.[30,31] Empiric use of amphotericin B deoxycholate has been supplanted by less toxic agents. Choices include polyenes, triazoles, and echinocandin classes of antifungal agents.[30,120]

Two prospective studies suggested that fluconazole is an equally effective but less toxic alternative to amphotericin B when it is given as empiric antifungal therapy in patients with cancer who have prolonged fever and neutropenia.[121,122] The azoles, however, may be less active than amphotericin B against some species and should not be used as empiric therapy in patients who are receiving fluconazole prophylaxis or have had recent azole exposure. Fluconazole has no useful activity against *Aspergillus* and has less activity than amphotericin B against *C. tropicalis, C. krusei, Candida lusitaniae*, and *C. glabrata*. Itraconazole and voriconazole have activity against *Candida* spp., *Aspergillus* spp., and some of the less common fungi, but no activity against Zygomycetes. Voriconazole compared favorably with liposomal amphotericin B in adult patients with cancer who had fever and neutropenia.[123] Newer azoles such as posaconazole and isavuconazonium sulfate provide broad activity against *Aspergillus* and *Mucorales* spp. The use of posaconazole is approved by the Food and Drug Administration for prophylaxis against invasive *Aspergillus* and *Candida* infections in immunocompromised patients 13 years of age and older. Posaconazole is distinct in having been successfully used in salvage treatment of infections caused by Zygomycetes, but its efficacy as an empiric antifungal agent in febrile and neutropenic patients with cancer has not been evaluated.

Considerable interest has been expressed in preparations of liposomal or lipid-associated amphotericin because of lower toxicity. In the only randomized, double-blind trial comparing liposomal amphotericin with conventional amphotericin B as empiric antifungal therapy, outcomes were similar with respect to survival, resolution of fever, and discontinuation of study drug because of toxic effects or lack of efficacy.[124] Liposomal amphotericin B was associated with fewer breakthrough fungal infections, less infusion-related toxicity, less nephrotoxicity,[124] and lower hospital costs.[125]

The echinocandins (i.e., caspofungin, micafungin, anidulafungin) are large lipopeptide molecules that are inhibitors of β-(1,3)-glucan synthesis, which is essential for fungal cell wall synthesis. Both in vitro and in vivo, the echinocandins are rapidly fungicidal against most *Candida* spp. and are fungistatic against *Aspergillus* spp., but they intrinsically are not active against Zygomycetes, *Cryptococcus neoformans*, or *Fusarium* spp.[126] Because the drug target is not present in mammalian cells, adverse events are generally mild, including (for caspofungin) local phlebitis, fever, abnormal serum hepatic enzymes, and mild hemolysis. In a prospective randomized, double-blind trial comparing the efficacy and safety of caspofungin with that of liposomal amphotericin B, caspofungin was as effective as and generally better tolerated than liposomal amphotericin B when it was given as empiric antifungal therapy in patients with persistent fever and neutropenia.[127] Caution is warranted in using echinocandins for the treatment of *C. parapsilosis* infection, given that patients with *C. parapsilosis* infection had persistently positive blood culture results when they were treated with caspofungin but achieved clearance when treated with amphotericin.[128] This agent is licensed for adult use, and the optimal caspofungin dosing for pediatric patients is not known. One small prospective study investigated the pharmacokinetics and safety of caspofungin in children and demonstrated that a caspofungin dose of 50 mg/m^2/day provided comparable exposure to that of adult patients treated with 50 mg/day without any serious drug-related adverse events or toxicity[129] (see Chapter 293). The newer echinocandins, micafungin and anidulafungin, also appear to be well tolerated in pediatric oncology patients.[130,131] In the absence of potential mechanistic antagonism with other antifungal drugs and a mild adverse event profile, combination antifungal therapy could become a general feature of echinocandin use, particularly for invasive aspergillosis.

Preemptive antifungal therapy has been shown to be a safe and effective management alternative in a subset of adult patients with continued fever and neutropenia. Prospective clinical trials have demonstrated that high-risk adults receiving prophylaxis against *Candida* spp. who remain febrile but are clinically stable and have no evidence of invasive fungal infections based on lack of clinical or radiologic (chest and sinus computed tomography) signs, negative serum mycologic assays (e.g., *Aspergillus* galactomannan, β-[1,3]-D glucan, fungal polymerase chain reaction tests), and sterile cultures may be closely monitored without starting empiric antifungal therapy.[132,133] The performance characteristics of the *Aspergillus* galactomannan assay in children are improved when this test is performed serially in the highest-risk children and during periods of neutropenia.[134,135] Additional data are required regarding the utility of mycologic assays in high-risk children hospitalized with fever and neutropenia; data are insufficient to construct an evidence-based preemptive antifungal treatment algorithm in the management of the high-risk child with persistent fever and neutropenia.

Risk Stratification

The following are extrapolated from the published literature as key factors increasing the risk of infectious complications in patients with fever and neutropenia: (1) anticipated duration of neutropenia[136]; (2) significant medical comorbidity[136,137]; (3) cancer status and cancer type; (4) documented infection on presentation; (5) evidence of bone marrow recovery[138,139]; and (6) height of fever.[8,138] The prospect of accurately and reliably identifying patients with fever and neutropenia who are at lower risk for complications is a desirable goal and integral to optimizing antimicrobial management strategies. In adults with fever and neutropenia, a risk stratification schema proposed from the Multinational Association of Supportive Care in Cancer (MASCC) has been validated and applied to identify adults with fever and neutropenia who are at low risk for complications and are thereby candidates for oral antimicrobials and outpatient therapy.[140] The MASCC score has not been evaluated in the pediatric oncology population. Multiple risk prediction studies have been conducted,[141] and certain low-risk stratification schemas have been validated in children.[138,139,142–147] However, no consensus exists on a single risk stratification schema and management algorithm that can be reliably and universally incorporated across pediatric clinical centers.

Investigations of oral antibiotic therapy have used many antibiotic regimens (pefloxacin,[148] ofloxacin,[149–153] ciprofloxacin,[154–156] cefixime,[157,158] moxifloxacin[159]) for empiric coverage in low-risk febrile and neutropenic patients with cancer. Although the results of these studies are encouraging, many of the clinical trials were statistically underpowered and limited by methodologic issues. Two large, prospective randomized studies of low-risk patients evaluated the efficacy of oral ciprofloxacin in combination with oral amoxicillin-clavulanate with more conventional parenteral antibiotic therapies in an inpatient setting.[160,161] Although the relative efficacies of oral and intravenous regimens were comparable in both these clinical trials, limited experience precludes this practice as an established standard for treating low-risk pediatric patients. A prospective, outpatient trial in children with low-risk febrile neutropenia that compared oral amoxicillin-clavulanate and ofloxacin with intravenous ceftriaxone and amikacin also found that outpatient therapy was safe, with no differences in outcome in oral versus intravenous therapy.[162,163] Outpatient and oral antibiotic management of children with low-risk fever and neutropenia was found to be effective in a meta-analysis.[164] When analyzing the spectrum of infections in a large cohort of low-risk febrile neutropenic patients (757 episodes of fever and neutropenia) at MD Anderson Cancer Center in Houston, Texas, investigators found that episodes of unexplained fever were predominant (58% of episodes), but both clinically documented and microbiologically documented infections were seen with equal frequency (21% respectively).[165] Among microbiologically documented infections, gram-positive (49%), gram-negative (36%), and polymicrobial (15%) infections were documented. Thus, although these patients were considered at low risk for developing infectious complications, many patients developed serious infections necessitating broad-spectrum antibiotic therapy.

Recombinant Human Colony-

Stimulating Factors

The use of hematopoietic growth factors, such as granulocyte-macrophage colony-stimulating factor (GM-CSF) and granulocyte colony-stimulating factor (G-CSF), has been implemented widely in the management of neutropenia in patients with cancer and bone marrow transplants. Both G-CSF and GM-CSF have been evaluated as adjuncts to chemotherapy to assist bone marrow reconstitution and possibly prevent neutropenia and reduce infectious complications.

The use of CSFs as adjunctive treatment for fever and neutropenia has been studied in clinical trials. Primary use of G-CSF was shown to lower the incidence of febrile neutropenic episodes by approximately 50% in 3 randomized studies in which the incidence of fever and neutropenia in the control group was >40%. Prophylactic use of G-CSFs in adults reduced the risk of fever and neutropenia episodes, as well as infection-related mortality rates.[166] A meta-analysis of 13 studies revealed that the use of CSFs in patients with fever and neutropenia reduced the amount of time spent in the hospital and the neutrophil recovery period; the overall mortality rate was not affected by the use of CSFs.[167,168] A meta-analysis of randomized, controlled trials using prophylactic CSFs in children with cancer found a reduction in the rate of fever and neutropenia by 20%, decreased duration of both neutropenia and hospitalization, and reduction in documented infections rates by 22%. However, the use of CSFs did not reduce infection-related mortality rates.[169] Data are inconsistent regarding whether significant clinical benefits of starting CSFs during an episode of fever and neutropenia (beyond shortening time to resolution of neutropenia) exist to warrant routine use.[170,171]

Guidelines published by the American Society of Clinical Oncology recommend the use of G-CSF as primary prophylaxis, before the onset of neutropenia, if the expected incidence of fever and neutropenia is ≥40% (rate seen in control patients in the randomized trials), but not routinely at presentation with fever and neutropenia.[172] Clinical practice guidelines published by the Infectious Disease Society of America and the European Organisation for Research and Treatment of Cancer suggest consideration of prophylactic G-CSF when the anticipated risk of fever and neutropenia is ≥20%, but not for treatment of established fever and neutropenia.[30,173]

Secondary use of G-CSF or GM-CSF in subsequent cycles of chemotherapy has not demonstrated disease-free or overall survival benefits when the dose of chemotherapy was maintained. Therefore reduction in chemotherapy dose should be considered the primary therapeutic option in a patient who experiences neutropenic fever or severe or prolonged neutropenia after the previous cycle of treatment. If G-CSF is administered within the first few days of chemotherapy for the initial induction or the first postremission course for acute lymphoblastic leukemia, the duration of neutropenia of <1000/mm^3 can be shortened by approximately 1 week. These studies and guidelines for the use of hematopoietic growth factors are summarized in a consensus paper by the American Society of Clinical Oncology.[172]

Prevention

Preventive strategies have been evaluated, including the use of hematopoietic growth factors, isolation measures, active and passive immunization, and prophylactic antimicrobial regimens.

Active Immunization

Guidelines for vaccination of immunocompromised children, including children receiving cancer chemotherapy and HSCT recipients, have been published.[174–176] Annual inactivated influenza vaccination is routinely recommended for patients ≥6 months of age with hematologic and solid tumor malignant diseases. Although vaccination is safe, efficacy is reduced in patients receiving intensive chemotherapy (e.g., induction or consolidation in acute leukemia) or in patients receiving anti–B-lymphocyte antibodies. Killed virus or subunit vaccines are considered safe for even the most compromised patients, but the efficacy in these patients may be reduced. Inactivated vaccines (other than influenza) that are given during maintenance chemotherapy are not considered valid doses and must be given 3 months after completion of chemotherapy unless a protective antibody level is documented. Vaccine administration should be delayed for at least 6 months after receiving monoclonal antibodies directed against B lymphocytes. Children recovering from allogeneic bone marrow transplantation may acquire the immunity of their donor but generally should be regarded as unimmunized. Because antibody concentrations against vaccine-preventable diseases typically decline after HSCT, recipients are candidates for revaccination.[176] Generally, revaccination for both autologous and allogeneic HSCT recipients should begin 6 to 12 months after HSCT. However, pneumococcal conjugate and inactivated influenza vaccines can be administered as early as 3 and 4 months after HSCT, respectively. If influenza vaccine is given earlier than 6 months after HSCT, a second dose should be contemplated regardless of the conditioning regimen. Thereafter, lifelong seasonal influenza vaccination is recommended for all HSCT recipients. Live-virus vaccines can be administered 2 years after successful transplantation if the patient has no evidence of graft-versus-host disease and is not receiving immunosuppressive drugs. Vaccinations for family members, close household contacts, and healthcare workers is strongly recommended.

Passive Immunization

Passive immunization also has been evaluated. In certain circumstances, infection-specific or hyperimmune globulins have proved to be particularly helpful, as in the case of postexposure use of varicella-zoster immune globulin (VariZIG) in persons who lack evidence of immunity to varicella and in whom varicella vaccine is contraindicated. VariZIG reduces the incidence of primary varicella and its complications in nonimmune persons if it is given ideally within 96 hours and up to 10 days after exposure.[177] Approval by the Food and Drug Administration was based on the clinical use of varicella immunoglobulin in exposed immunocompromised children that resulted in fewer clinical varicella cases and less severity in the subgroup of children who did develop disease, compared with historical controls. Because protection lasts for only 3 to 4 weeks after VariZIG administration, repeated doses may be necessary in the setting of community outbreaks and repeated exposure. Patients receiving high-dose immune globulin intravenous (≥400 mg/kg IGIV) are likely protected if the dose of the IGIV was administered in the preceding 3 weeks. IGIV can be used as prophylaxis for measles in susceptible patients during epidemics.

Prophylactic Antimicrobial Therapy

Many clinical trials have focused on the use of prophylactic antibiotics to prevent infections in neutropenic patients without fever. The oral fluoroquinolone antibiotics have been investigated because of their good bioavailability and broad activity against aerobic gram-negative bacteria. A meta-analysis of published randomized controlled trials of fluoroquinolone prophylaxis (18 trials with 1408 patients) found that prophylaxis significantly reduced the incidence of gram-negative bacterial infections, total infections, and fevers but did not alter the incidence of gram-positive infections or infection-related deaths.[178] A large, randomized, prospective trial evaluating the use of oral levofloxacin (500 mg daily) in adults with cancer before anticipated chemotherapy-induced neutropenia showed that the levofloxacin-treated group had a lower rate of microbiologically documented infections did than the placebo group. The mortality rates were similar in the 2 groups, and the effect of prophylaxis was similar between patients with acute leukemia and those with solid tumors or lymphomas.[179] Two studies evaluating the use of prophylactic oral levofloxacin (500 mg daily) in patients receiving chemotherapy for either solid tumors or lymphoma[180] or hematologic malignant diseases[181] both showed a reduction in documented infections. A meta-analysis of antibiotic prophylaxis in neutropenic patients with cancer (95 trials performed between 1973 and 2004) concluded that antibiotic prophylaxis (various antibiotic regimens) compared with placebo or no treatment significantly decreased the risk for death.[182] When trials that used fluoroquinolone prophylaxis (52 trials) were separately analyzed, a significant reduction was observed in the risk for all cause-mortality, as well as infection-related mortality, fever, clinically documented infections, and microbiologically documented infections. Many of these studies reported increasing rates of antimicrobial resistance to fluoroquinolones.[179,181,182] Thus, if fluoroquinolone prophylaxis is implemented, vigilant monitoring of the incidence of BSI (specifically gram-negative BSI) is important to detect the loss of efficacy of fluoroquinolone prophylaxis.

Fluoroquinolone prophylaxis should be considered for high-risk adult patients in whom severe neutropenia (ANC ≤ 100 cells/mm^3) is expected to last for more than 7 days.[30,175] Data on fluoroquinolone prophylaxis is children are less robust and raise concerns about adverse effects on antibiotic resistance patterns. The use of ciprofloxacin prophylaxis in 95 children with acute lymphoblastic leukemia or acute myeloid leukemia led to a 23% reduction in fever and neutropenia episodes in patients with acute lymphoblastic leukemia during induction chemotherapy, but not in patients receiving consolidation or in those with lymphoma.[183] Of concern, after only 2 weeks, the proportion of ciprofloxacin-resistant gram-negative bacteria colonizing patients who received fluoroquinolone prophylaxis was 95% compared with 27% of those patients randomized to receive placebo. Significantly increased rates of emerging resistance after fluoroquinolone use have been documented in other pediatric studies.[4] Given an incidence of gram-negative BSI of 10% to 15% in this population, it was estimated that fluoroquinolone prophylaxis would need to be administered unnecessarily in 96 to 97 patients to prevent an episode in 3 to 4 patients.[184] Routine fluoroquinolone prophylaxis precludes its empiric use for fever and neutropenia.[185,186] Further study in children is necessary before widespread use is adopted.

In meta-analyses, antifungal prophylaxis was found to reduce superficial and invasive fungal infections, fungal infection–related morbidity, and mortality rates in some patients, particularly patients with prolonged neutropenia or HSCT receipt.[187,188] Thus, prophylaxis against *Candida* species is recommended in patients at high risk for invasive infection, including allogeneic HSCT recipients and patients undergoing remission-induction or salvage-induction chemotherapy for acute leukemia. Broad use of fluconazole prophylaxis has changed the epidemiology of infections with *Candida* spp. In several studies investigating fluconazole, infections with fungi known to be resistant to fluconazole (i.e., *Aspergillus* or other molds and non-*albicans Candida* spp. such as *C. glabrata*) have been major causes of morbidity and mortality.[121,189,190] Antifungal prophylaxis with agents active against molds such as voriconazole or posaconazole should be considered in selected patients, including those with a previous history of

Aspergillus infection, patients with a prolonged period of neutropenia before HSCT, patients with anticipated prolonged neutropenia of >2 weeks, and HSCT recipients with acute graft-versus-host disease receiving augmented immunosuppression, as well as in centers where the rate of invasive aspergillosis is ≥6%.[30,191,192] The potential for serious drug interactions with azole agents necessitates close monitoring, especially when these drugs are given concomitantly with other medications (e.g., vincristine, high doses of cyclophosphamide) that are metabolized by cytochrome P450 isoenzymes.

The incidence of PCP in children with cancer can be decreased by the use of trimethoprim-sulfamethoxazole, which has become a standard part of medical management.[193,194] The incidence of recurrent herpes simplex disease in patients receiving intensive chemotherapy or bone marrow transplantation has been reduced with the prophylactic use of acyclovir.[195] In addition, the use of viral surveillance and preemptive ganciclovir therapy in preventing cytomegalovirus disease and the use of acyclovir or valacyclovir in preventing varicella-zoster virus reactivation after bone marrow transplantation has been shown to be effective.[196,197]

Infections in Children With Cancer

Monica I. Ardura, Andrew Y. Koh

Approximately one third of pediatric patients with cancer who have fever and neutropenia have a clinically or microbiologically proven site of infection. Table 98.1 summarizes documented infections identified in 3 large clinical trials of empiric antibiotic therapy administered to patients admitted to the National Cancer Institute for fever during episodes of neutropenia.[1–3]

TABLE 98.1

Documented Sites of Infection in Patients with Cancer, Fever, and Neutropenia

Site or Type of Infection	Pizzo et al.[1] No. (%)	Pizzo et al.[2] No. (%)	Freifeld et al.[3] No. (%)	Total No. (%)
Bloodstream	81 (43)	109 (27)	20 (17)	210 (29)

Diagnosis and Management of Specific Clinical Syndromes of Infection

Catheter-Associated Bacteremia

Several series evaluating the use of central venous catheters in patients with cancer confirmed that these devices increase the incidence of bloodstream infection (BSI), regardless of the level of bone marrow suppression.[4,5] Although gram-positive organisms, particularly coagulase-negative staphylococci, emerged as the predominant pathogens, almost any bacteria can be responsible for central line–associated BSI (CLABSI) bacteremia. Fungi, most often *Candida* spp., also can cause CLABSI and are difficult to eradicate without removal of the contaminated device.[6,7] Mixed flora bacteremia should prompt an investigation to identify a causative event (e.g., swimming with the catheter unprotected, dropping of catheter tubing into bathwater, chewing on catheter tubing by young children, disconnection of catheter caps or tubing) so that appropriate education can be provided.

In evaluating children for CLABSI, cultures should be obtained from all lumens of a multilumen device. Because of the increased risk of CLABSI, empiric antibiotics may also be warranted in non-neutropenic patients with central venous catheters who have fever with no localizing findings. The choice of agent used for empiric antibiotic therapy in children with cancer should have a broad spectrum of activity, and take into account the severity of illness, associated neutropenia, history of infection or colonization with multidrug-resistant bacteria, and antimicrobial prophylaxis regimens. Vancomycin may not be necessary empirically unless the patient has evidence of soft tissue infection at the catheter site or elsewhere, clinical instability, or a history of a resistant gram-positive pathogen.[8–10]

Infection of soft tissue at the catheter site can be confined to the skin immediately surrounding the exit site of a catheter or can involve deeper soft tissue around the subcutaneously tunneled portion of the catheter or access port. Localizing findings in a neutropenic child should be considered evidence of infection, thus mandating hospitalization and administration of broad-spectrum antibiotics, including an antistaphylococcal agent. Induration, erythema, tenderness, or fluctuance along the subcutaneous tunnel tract generally requires removal of the catheter, debridement of infected tissue, and systemic antibiotic therapy.

Catheter management (salvage or removal) depends on the pathogen, the type of catheter, the patient's clinical manifestations, and complications. Most episodes of bacterial CLABSI can be successfully treated with the catheter in place, even when multiple organisms are identified.[4,11] Although current guidelines recommend the addition of antibiotic lock therapy for catheter salvage, data on an additional benefit of antibiotic or ethanol lock therapy in pediatric oncology patients with CLABSI are inconclusive, warranting prospective study.[12,13] Removal of the catheter is recommended if the patient has erythema or exudate at the catheter site (concerning for a catheter pocket or tunnel infection), bacteremia with certain pathogens, persistence of bacteremia despite 72 hours of appropriate antimicrobial therapy, or the presence of concomitant endocarditis, suppurative thrombophlebitis, or metastatic infection.[14] Specific organisms require removal of the catheter: *Staphylococcus aureus*,[11,12] *Bacillus* spp.,[14,15] *Mycobacterium* spp.,[16] *Pseudomonas aeruginosa* and multidrug-resistant gram-negative bacteria (e.g., *Acinetobacter* spp.), and fungi (including *Candida* spp.)[6,7,9,14] Polymicrobial infections may require removal of the catheter.

Skin Infections

Cutaneous infections are common in immunocompromised patients. These infections accounted for 22% to 33% of infections in an older series,[17] as well as 16% of infections present at the time of hospitalization for fever and neutropenia in another study.[3] Infections of the skin can be caused by bacteria, fungi, or viruses.

Bacteria.

Bacterial skin infections usually are caused by staphylococci or streptococci. In immunocompromised patients, both gram-positive and gram-negative bacteria, including enteric organisms and *Pseudomonas,* can be isolated either from the blood or from material obtained from fine-needle aspiration of the area of cellulitis.[18] *P. aeruginosa* infection classically is associated with the severe necrotic skin lesion *ecthyma gangrenosum* (Fig. 98.1), although invasive infections with other gram-negative organisms, staphylococci, mycobacteria, and fungi can cause ecthyma gangrenosum. Empiric therapy for suspected bacterial cellulitis should provide broad-spectrum coverage. Every effort should be made to establish a microbiologic diagnosis; new skin lesions should be examined using biopsy and culture.

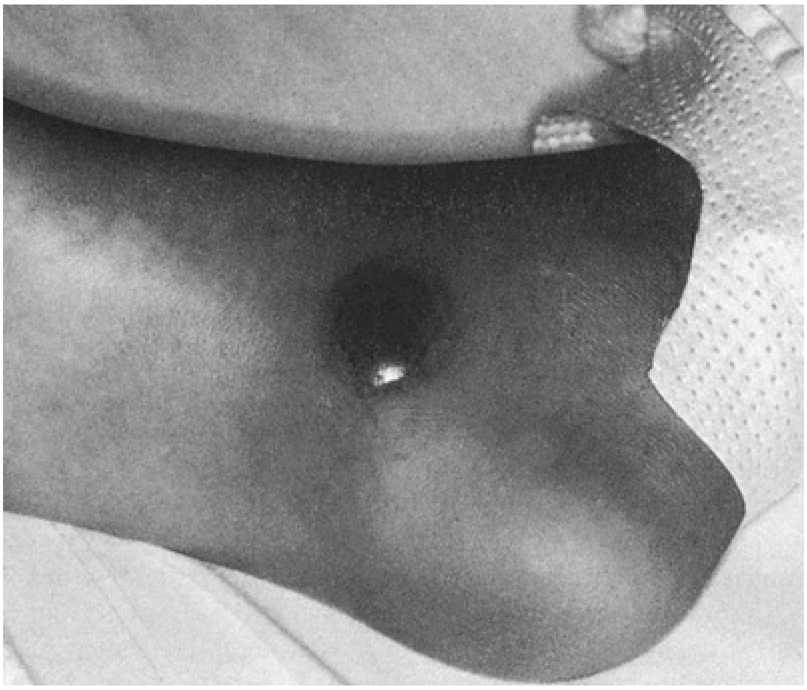

FIGURE 98.1 Ecthyma gangrenosum in an 8-year-old boy with newly diagnosed acute lymphocytic leukemia, fever, and bacteremia caused by *Pseudomonas aeruginosa.*

Fungi.

Fungal pathogens including *Candida, Aspergillus, Fusarium, Scedosporium,* and agents of mucormycosis can cause cutaneous lesions either as isolated, primary infections or as manifestations of disseminated infection.[19] Routine blood and fungal blood cultures and tissue histologic examination and culture should be obtained. Black, rapidly progressing, necrotic eschars should prompt immediate evaluation for fungal infection. Tender, erythematous skin nodules or pustules can develop during candidemia; examination can aid diagnosis while awaiting culture results. Superficial cultures of suggestive skin lesions may not provide adequate material for diagnosis of fungal infections; biopsy generally is more useful. A cutaneous fungal infection resulting from *Aspergillus* or other molds often is a manifestation of hematogenous spread or local angioinvasive infection, requiring surgical debridement in addition to prolonged antifungal therapy.

Viruses.

Cutaneous viral infections can result from either primary infection or viral reactivation. Herpes simplex virus (HSV) and varicella-zoster virus (VZV) can cause painful or pruritic vesicular lesions that can become secondarily infected. The diagnosis is confirmed by unroofing a fresh vesicle, scraping the base of the lesion, and testing the sample by direct fluorescent antibody or polymerase chain reaction (PCR) for HSV and VZV. Differentiation is important because VZV infection requires higher doses of acyclovir (10 mg/kg/dose or 500 mg/m^2/dose every 8 hours) than does HSV infection. Acyclovir prophylaxis has demonstrated benefit in preventing reactivation in HSV- and VZV-seropositive recipients of allogeneic hematopoietic cell transplantation (HCT) and in patients receiving induction therapy for acute leukemia.[9,20–22]

Patients with cancer who develop primary varicella, especially patients who are actively receiving chemotherapy, are at increased risk of serious disseminated disease, including giant cell pneumonia, encephalitis, hepatitis, and purpura fulminans. Rates of dissemination and subsequent mortality (estimated as 7% to 20% in untreated patients[23]) have been reduced by rapid initiation of intravenous acyclovir therapy.[24] Although recurrent disease in the form of herpes zoster is rarely associated with severe complications when VZV infection remains localized to the skin, dissemination occurs in up to 25% of patients with immunocompromising conditions.[25] Severe abdominal pain, back pain, or evidence of inappropriate antidiuretic hormone secretion can herald multisystem involvement, indicating an urgent need to initiate intravenous acyclovir therapy.[26]

Scabies.

A severe variant of scabies (caused by *Sarcoptes scabiei)*, called Norwegian or crusted scabies, occurs in immunodeficient patients, especially patients with leukemia or lymphoma, and is characterized by the presence of 10^3 to 10^6 viable mites, resulting in widespread, hyperkeratotic, crusted lesions. This form of scabies is highly contagious and also can be recalcitrant to standard topical scabicidal therapy. Oral ivermectin is highly effective for treating both routine scabies and Norwegian scabies after a single administration, although additional treatment often is given.[27,28]

Pulmonary Infections

The lungs are the most common sites of localized infection in patients with neutropenia, and pulmonary infection in this population produces a wide variety of symptoms, signs, and radiographic appearances. Table 98.2 summarizes causative agents suggested by radiographic findings.

TABLE 98.2

Causes of Pulmonary Processes in Patients with Cancer as Suggested by Radiographic Abnormality

Radiographic Manifestation	Infectious Cause	Noninfectious Process
Focal consolidation (lobar or segmental)	Bacteria (routine and nosocomial pathogens) *Legionella* Oral flora (aspiration and postobstructive) *Mycobacterium tuberculosis* Fungi (*Cryptococcus, Histoplasma, Coccidioides*)	Pulmonary hemorrhage Pulmonary infarction Atelectasis Radiation pneumonitis Drug-related pneumonitis Tumor
Diffuse interstitial infiltrate	Viruses *Pneumocystis jirovecii* Mycobacteria, including miliary tuberculosis Disseminated fungi (*Cryptococcus, Histoplasma, Coccidioides*) *Mycoplasma* *Chlamydophila*	Pulmonary edema Adult respiratory distress syndrome Drug-related pneumonitis Radiation pneumonitis Lymphangitic metastasis Lymphocytic interstitial pneumonitis (HIV)
Nodular infiltrate (with	Molds: *Aspergillus, Mucor, Fusarium*	Tumor

or without cavitation)	Bacteria (especially *Staphylococcus aureus, Pseudomonas, Klebsiella,* anaerobic bacteria), *Nocardia* Mycobacteria, including *M. tuberculosis* Viruses (e.g., CMV, HSV, VZV, EBV, RSV)	

CMV, cytomegalovirus; EBV, Epstein-Bar virus; HIV, human immunodeficiency virus; HSV, herpes simplex virus; RSV, respiratory syncytial virus; VZV, varicella-zoster virus.

Localized Infiltrates

Acute localized infiltrates at the onset of fever in a patient with cancer, with or without neutropenia, are most often caused by bacterial pathogens. Because both community-acquired and healthcare-associated pathogens can be responsible for pneumonia in neutropenic patients, initial antibiotic therapy should provide coverage for organisms such as *Streptococcus pneumoniae* and *Haemophilus influenzae,* as well as *Pseudomonas* spp. and other gram-negative bacteria. *Legionella* also is considered in febrile, immunocompromised patients with patchy infiltrates. *Legionella* can colonize air conditioning equipment and showerheads and can be spread by aerosolization of contaminated water. Antigen testing of urine is sensitive and specific for *L. pneumophila,* serogroup 1. Patients with pulmonary metastases of cancers also can have an increased risk for postobstructive pneumonia resulting from mouth flora, including anaerobic bacteria. The antibiotic regimens used for empiric therapy for fever without localizing findings in a patient with neutropenia (e.g., fourth-generation cephalosporin, extended-spectrum penicillin, or carbapenem) are appropriate for initial management of pneumonia. In some cases, the addition of a macrolide or fluoroquinolone for possible *Mycoplasma* or *Legionella* infections is warranted. In children with clinical or imaging findings consistent with possible community-associated *Staphylococcus aureus* pneumonia, vancomycin or clindamycin should be added to the beta-lactam therapy.

Viruses, such as influenza and parainfluenza viruses, respiratory syncytial virus, and adenovirus, also can cause localized infiltrates in immunocompromised children, although a diffuse process is more common. In one study, respiratory viruses were detected in 52% of 50 episodes of fever in neutropenic children with negative bacterial cultures, though ascribing a causal role in the clinical illness is challenging.[29] Consideration of a viral infection can lead to specific therapy (e.g., as in influenza), but it does not obviate the need for broad-spectrum antibiotic therapy in a patient with neutropenia, fever, and a pulmonary infiltrate.

A patient with localized infiltrates who fails to respond to broad-spectrum antibiotics has broad differential diagnostic possibilities. Guidelines recommend bronchoalveolar lavage (BAL) fluid sampling in patients with fever, neutropenia, and an infiltrate of uncertain origin.[9] Infection resulting from fungi, *Nocardia,* mycobacteria (including *Mycobacteria tuberculosis*),[30] or antibiotic-resistant, healthcare-associated bacteria can manifest with localized infiltrates. Endemic fungi, *Histoplasma, Cryptococcus,* and *Coccidioides* also can cause localized pneumonitis in selected geographic regions and, in compromised hosts, can also be associated with extrapulmonary infection. The presence of *Candida* in upper respiratory tract or tracheal secretions, even in patients with pulmonary infiltrates, correlates poorly with causation because of the high frequency of colonization of the oral cavity and tracheobronchial tree. Blood culture results that are positive for *Candida* or typical retinal lesions of endophthalmitis are associated with disseminated infection, which can include pneumonia. In the absence of these findings, definitive diagnosis usually requires histopathologic confirmation.

The fungal pathogens of most concern in the patient with neutropenia include *Aspergillus, Fusarium,* agents of mucormycosis, *Scedosporium,* and *Trichosporon* because these organisms cause rapidly progressive, extensively destructive infection. Unlikely to be identified at the onset of neutropenia and fever, the finding of a progressive or new infiltrate, accompanied by fever, nonproductive cough or hemoptysis, and pleuritic chest pain, in a persistently neutropenic patient during broad-spectrum antibiotic therapy suggests the diagnosis of invasive fungal pneumonia (most frequently with *Aspergillus*). Computed tomography (CT) may reveal multiple pulmonary nodules (sometimes with cavitation) that are not readily apparent on routine chest radiographs.[31] The classic histopathologic findings in aspergillosis are invasion of the blood vessels with thrombosis and resulting infarction and hemorrhage. Whereas recovery of *Aspergillus* from the respiratory tract of patients without neutropenia can represent colonization, isolation of this organism in the setting of prolonged neutropenia and pulmonary infiltrate is highly predictive of invasive disease,[32] and is sufficient evidence for initiation of antifungal therapy. In biopsy-proven *Aspergillus* pneumonia, BAL has a recovery rate of only 50%, and transbronchial biopsy has a recovery rate of only 20%. Open lung biopsy may be required.[33,34] *Aspergillus* galactomannan testing on blood and BAL specimens can facilitate the diagnosis of invasive pulmonary aspergillosis in patients with hematologic diseases, with overall sensitivity and specificity for proven invasive aspergillosis of 71% and 89%, respectively.[35–39] Thus, a positive galactomannan assay coupled with a consistent CT appearance can suggest probable invasive aspergillosis in a neutropenic patient with cancer or a history of HCT[40]; a positive culture result of a specimen obtained from a normally sterile site remains the gold standard for proven infection. Other non–culture-based assays, including β-D-glucan and fungal PCR, show promise as adjuncts to diagnosis, but they remain investigational in pediatrics.[40a]

Voriconazole is considered the drug of choice for primary treatment of invasive aspergillosis based on the findings of an international, randomized, open-label trial demonstrating that voriconazole conferred a significant benefit of survival and overall therapeutic response compared with patients treated with amphotericin.[41–43] Liposomal amphotericin can be considered as alternative or salvage therapy.[44] The echinocandin agent caspofungin initially was approved for use in patients with refractory aspergillosis. A prospective study enrolling 90 patients with invasive aspergillosis who were refractory to (86%) or intolerant of amphotericin B, liposomal amphotericin B, or triazoles (14%) and who were treated with caspofungin showed a favorable response to caspofungin therapy in 45% of patients (50% with pulmonary aspergillosis and 23% with disseminated aspergillosis).[45] Although successful use of caspofungin as first-line monotherapy for invasive aspergillosis has been reported,[46,47] no randomized controlled trials comparing efficacy with other antifungal agents have been conducted. Finally, given few adverse effects and a theoretical lack of antagonism, combination therapy with voriconazole and an echinocandin for invasive aspergillosis can be considered.[48–50] Results of a randomized, double-blind, placebo-controlled trial in adults with hematologic malignant diseases and after HCT who had suspected or documented invasive aspergillosis demonstrated improved survival rates in patients who received combination therapy with voriconazole and an echinocandin compared with patients who received voriconazole monotherapy.[51] Other fungal pathogens, such as *Histoplasma capsulatum, Coccidioides immitis,* and *Cryptococcus neoformans,* can also cause focal infiltrates in patients with neutropenia who are receiving corticosteroid therapy or with epidemiologic exposures.[52]

Diffuse or Interstitial Infiltrates

Diffuse or interstitial infiltrates can represent a nonbacterial process, although both gram-positive and gram-negative bacteria can cause interstitial pneumonitis. In children not receiving antimicrobial prophylaxis, *Pneumocystis jirovecii* is the organism most often identified in the setting of diffuse, interstitial infiltrates. Historically, in children with leukemia during maintenance chemotherapy who did not receive prophylaxis, incidence rates of *Pneumocystis* pneumonia (PCP) were 2% to 22%.[53] The incidence of PCP in patients with cancer has been reduced substantially with the standard use of prophylactic trimethoprim-sulfamethoxazole (TMP-SMX). Nonetheless, *P. jirovecii* should be considered in children receiving corticosteroid therapy or in children with significant cell-mediated immune deficiency who have fever, nonproductive cough, tachypnea, and hypoxemia. In a review of oncology patients with confirmed PCP, 70% of patients became symptomatic while corticosteroid dosages were being tapered.[54] The chest radiograph in PCP typically reveals bilateral perihilar interstitial, or alveolar, infiltrates that spread to involve all lobes (Fig. 98.2), but virtually any radiographic pattern can occur. The diagnosis is established by microscopic findings of either cysts or trophozoites on smears of respiratory tract secretions obtained by sputum induction, BAL, or open lung biopsy. Because *Pneumocystis* cannot be cultured, and the sensitivity of microscopy is lower in patients who do not have human immunodeficiency virus (HIV) infection, additional assays have been applied, including *Pneumocystis* PCR and β-D-glucan assays, to improve diagnostic yield. *Pneumocystis* PCR performed on BAL or sputum specimens from non-HIV immunocompromised patients compared with conventional microscopy methods in one study showed sensitivity of 87% and specificity of 92% for PCP, with a negative predictive value of 100%.[55] A positive serum (1,3)-β-D glucan assay may be an early indicator of PCP and has been used clinically in children with malignant diseases; the assay has positive and negative predictive values of 61% to 64% and 98% to 99%, respectively.[56–58] In non-neutropenic patients with diffuse infiltrates who are unable to undergo BAL or biopsy, an empiric course of TMP-SMX can be considered.[59] Definitive therapy for PCP is TMP-SMX, 15 to 20 mg/kg/day divided into every 6 hour doses for 21 days. Patients with severe PCP who have an absolute contraindication to TMP-SMX therapy should receive pentamidine intravenously. Prednisone usually is given to patients with moderate or severe PCP concomitantly with antibiotic therapy. Other therapies found to be effective for PCP in HIV-infected patients include pentamidine, trimetrexate, atovaquone, and clindamycin plus primaquine. Recurrence of PCP or breakthrough infection is unusual in children with cancer receiving TMP-SMX prophylaxis, but it is reported in HIV-infected children.[60]

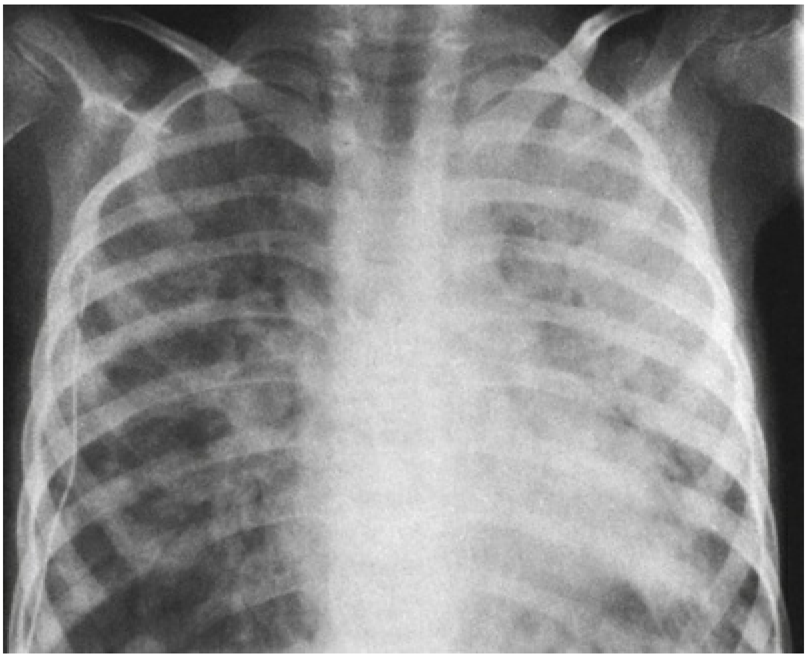

FIGURE 98.2 Chest radiograph showing bilateral interstitial and alveolar infiltrates in a child with acute lymphocytic leukemia and *Pneumocystis* pneumonia.

Viral infections also can cause pneumonia with diffuse or interstitial infiltrates. Whereas the common respiratory tract viruses cause more severe disease in immunocompromised patients, the most serious cases are caused by cytomegalovirus (CMV). CMV pneumonitis has been seen most often in patients receiving allogeneic bone marrow transplants, within the first 3 months after transplantation. Clinical presentation includes fever and rapidly progressive diffuse pulmonary infiltrates, often requiring ventilatory assistance. Risk factors for CMV pneumonitis include the presence of pretransplant CMV seronegativity in the donor and seropositivity in the, receipt of total body irradiation as part of the pretransplant regimen, and development of graft-versus-host disease.[61] The definitive diagnosis of CMV lower respiratory tract disease requires identification of viral cytopathic effect on lung tissue obtained by biopsy. Historically, CMV pneumonitis had a mortality rate of more than 80%. Antiviral treatment with ganciclovir or foscarnet has improved outcomes, with overall survival rates of 50% to 70%. The added benefit of pooled or CMV-specific intravenous immunoglobulin is less clear.[62–64] Standard practice in many transplant centers now includes preemptive strategies including surveillance testing (quantitative CMV DNA or RNA PCR tests) and preemptive therapy with intravenous ganciclovir for patients who have CMV isolated from any site during the early post-HCT period.[21,65]

Other herpesviruses, particularly VZV and HSV, can cause diffuse pneumonitis in patients with cancer. Respiratory syncytial virus also can cause severe lower respiratory tract disease with a high mortality rate, notably in patients undergoing therapy for acute myelogenous leukemia or after HCT.[66,67] Parainfluenza virus, influenza virus (including H1N1), human metapneumovirus, adenovirus, and human herpesvirus 6 can cause interstitial pneumonitis in pediatric patients with cancer.[68,69] Respiratory virus detection before HCT, even of rhinovirus alone, has been associated with lower survival rates at day 100.[70]

Infections of the Ears and Sinuses

Patients who have been hospitalized or who are receiving chemotherapy may have altered microbial flora. In addition to the usual bacterial pathogens responsible for otitis media (*S.*

pneumoniae, H. influenzae, Moraxella catarrhalis), nosocomial pathogens (such as gram-negative organisms) must be considered. In the neutropenic child, ear infections can be accompanied by pain, with minimal erythema of the tympanic membrane and canal. Malignant otitis externa resulting from invasive infection of the auditory canal with *P. aeruginosa* (and occasionally invasive fungi) occurs more commonly in patients with diabetes mellitus or patients receiving corticosteroids, but it also is seen in patients receiving chemotherapy and requires aggressive debridement and intravenous antimicrobial therapy.

Although mastoiditis is an uncommon infection in pediatric patients with cancer, those children with anatomic abnormalities of the middle ear and children with prolonged neutropenia are at increased risk. Fungi (particularly *Aspergillus*) can cause mastoiditis in neutropenic patients. Surgical debridement usually is required for cure.[71]

The paranasal sinuses also can become infected with typical pathogens or the altered bacterial flora in hospitalized patients. Sinusitis was found more commonly in children with hematologic malignant diseases than in those with solid tumors in one series, and 41% of 91 children with acute lymphoblastic leukemia had abnormal sinus radiographs at the time of induction chemotherapy.[72] Children with tumors involving the sinuses (e.g., nasopharyngeal carcinoma, Burkitt lymphoma, rhabdomyosarcoma) are at particular risk for recurrent or chronic sinusitis; distinguishing between progressive or necrotizing tumor and infection is challenging. Sinus radiography and CT are helpful tools in the diagnosis. Broad-spectrum antibiotics, including an agent with activity against anaerobic organisms, are necessary for treatment of sinusitis in neutropenic patients. If symptoms do not improve within 48 to 72 hours of empiric antibiotic therapy, aspiration or biopsy should be performed.

Patients who remain neutropenic for more than 7 days are at increased risk of fungal infection, including sinusitis. In a series of fungal sinusitis in children, facial pain or headache, fever, facial swelling (which developed in 50% of patients), and abnormal findings on sinus radiographs were the most common manifestations.[72] In a 10-year retrospective analysis of invasive fungal sinusitis, *Aspergillus flavus* accounted for >50% of cases, and periorbital swelling (41% of patients) was the most common presenting symptom.[73] Other fungal pathogens include *Mucor, Fusarium, Scedosporium, Rhizopus,* among others. A small, blackened eschar within the nose or sinus can be the first manifestation, with rapid progression, significant tissue invasion, necrosis secondary to vascular thrombosis, and ultimate extension into the orbits or brain. Obtaining biopsy material for histopathologic examination and culture is necessary to establish the diagnosis definitively. Management of rhinocerebral fungal infection requires aggressive surgical debridement and longterm therapy with voriconazole for *Aspergillus* sinusitis and amphotericin B and posaconazole considerations for zygomycosis.

Gastrointestinal Tract Infections

Underlying diseases and the cytotoxic and radiation regimens used in therapy predispose pediatric patients with cancer to alterations of the gastrointestinal mucosa that lead to local infections and portals of entry for resident microorganisms.

Mucositis and Esophagitis

Mucositis can range in severity from isolated, small oral ulcers to extensive mucosal sloughing of the oral cavity and more distal gastrointestinal tract. A recognizable complication of mucositis is necrotizing or marginal gingivitis, characterized by a periapical line of erythema and tenderness. Because this condition presumably results from anaerobic infection, empiric antibiotic therapy should include an effective agent (e.g., clindamycin, metronidazole, piperacillin-tazobactam, or meropenem). In addition, children who have had prolonged hospitalization or have received broad-spectrum antibiotics can have oral colonization with gram-negative organisms or fungi. Chemotherapy-induced mucositis also can become superinfected with *Candida, Aspergillus,*[74] or HSV. A Gram stain of scrapings (swab or tongue depressor) may identify yeast or hyphae, and immunofluorescent stain, PCR, or culture may confirm HSV infection. Mild *Candida* infection may respond to topical treatment with clotrimazole troches, but fluconazole, voriconazole,[75] caspofungin,[76–78] or amphotericin B usually is given because stomatitis can lead to locally invasive or disseminated fungal infection, or both. Oral or intravenous acyclovir is given for HSV stomatitis. Because 70% to 80% of children with a past history of HSV infection have reactivation during induction chemotherapy for leukemia or after HCT, oral acyclovir is given prophylactically during the high-risk period of leukopenia.[79] Septicemia caused by α-hemolytic streptococci can complicate mucositis and has high rates of shock and central nervous system (CNS) infection. Penicillin nonsusceptibility as high as 75% is reported in such cases.[80]

Although the differential diagnosis of substernal burning chest pain and odynophagia includes both infectious and noninfectious causes of esophagitis, establishing a specific cause can be difficult. Neither barium swallow nor endoscopic visualization reliably distinguishes among *Candida,* HSV, and noninfectious causes (e.g., mucositis secondary to chemotherapy or radiation). In one study, 21 of 22 patients with cancer who had a clinical and microbiologic diagnosis of oral candidiasis also had endoscopic and microbiologic findings diagnostic of candidal esophagitis, a finding suggesting that oropharyngeal candidiasis can represent a reliable marker for esophageal candidiasis in patients with cancer.[81] Definitive diagnosis, however, requires endoscopically performed biopsy and culture. When biopsy is considered too risky (e.g., a patient with a platelet count of $<50,000/\text{mm}^3$), a sequential approach can begin with empiric azole therapy (for *Candida* esophagitis), and if there is a lack of clinical improvement within 48 hours, change to amphotericin or caspofungin. Failure to improve within 48 hours of amphotericin or caspofungin makes *Candida* spp a less likely cause of esophagitis, and endoscopic biopsy should be reconsidered. If a biopsy cannot be performed, an empirical trial of acyclovir for presumptive HSV esophagitis could be considered. In the patient without neutropenia, infectious causes of esophagitis are uncommon; symptomatic treatment with antacids or histamine-blocking agents can be appropriate.

Intra-Abdominal Infections

The epidemiology of infectious diarrhea in children with fever and neutropenia is not well described. Infectious causes are broad, but most common viruses, including norovirus, enterovirus, adenovirus, and rotavirus, are responsible. More severe or protracted illness and prolonged viral shedding are expected in immunocompromised patients, especially in HCT recipients.[82] CMV also can cause severe colitis in HCT recipients and in patients receiving anti-CD52 monoclonal antibody therapy; case reports also describe CMV-associated colitis in patients receiving systemic chemotherapy for hematologic malignant diseases and lymphomas.[83,84] A history of travel, food consumption, water exposure (water park, well water), and animal exposure should be sought in children with fever and acute diarrhea. Fever and bloody diarrhea make the possibility of bacterial enteritis more likely, and stool samples should be tested by culture or PCR. Evaluation for parasitic infections (e.g., enzyme immunoassays for *Giardia* and *Cryptosporidium*, stool ova and parasite testing) is determined by exposure history.

Clostridium difficile Infection.

Pseudomembranous or antibiotic-associated colitis can follow antibiotic administration for empiric therapy in febrile neutropenic patients. Many patients become colonized with *Clostridium difficile* during hospitalization and can have prolonged shedding.[85] The incidence of *C. difficile* infection in hospitalized children is 15-fold greater in children with cancer compared with children without cancer.[86–88] Symptoms of *C. difficile* disease range from mild abdominal pain to severe bloody colitis. Diarrheal stool samples should be tested for *C. difficile* toxin whenever diarrhea or abdominal pain develops in a patient with neutropenia. Metronidazole is the drug of choice for the initial episode of mild to moderate infection, and oral vancomycin is given for more severe infections.[89] Children with malignant diseases have a higher risk for recurrent disease.[90] Treatment of first recurrence usually is with the same regimen as for the initial episode, but additional recurrences generally are treated with oral vancomycin therapy using a tapered regimen.[89] A trial of adding rifampicin to metronidazole therapy did not show a trend toward better efficacy.[91] Nitazoxanide[92,93] and teicoplanin[94] are potential alternatives to traditional therapy.

Typhlitis.

The immunosuppressed patient with cancer is at increased risk of intra-abdominal infections because of invasion or obstruction of the bowel by tumor, extension of mucosal ulcerations, or sloughing secondary to chemotherapy. Typhlitis, or neutropenic cecitis, is a necrotizing process involving the cecum and terminal ileum that is seen almost exclusively in patients with cancer who have profound neutropenia (most often associated with treatment of acute myeloid leukemia).[95] Additional risk factors identified in children include the presence of mucositis, HCT, and receipt of chemotherapy in the preceding 2 weeks.[96] Typhlitis manifests with nausea, vomiting, diarrhea, and abdominal pain localized to the right lower quadrant (mimicking appendicitis) that can become generalized and usually is accompanied by fever and systemic symptoms. Because of neutropenia, many patients with peritonitis lack classic signs.[97] Concomitant bacteremia or fungemia can occur. Plain radiographs are nonspecifically abnormal unless free air or intramural pneumatosis is noted. Abdominal ultrasound examination or CT can better demonstrate cecal wall thickening, pericecal edema, fat stranding, and intramural pneumatosis of the cecum. Histopathologic examination of the bowel reveals infiltration of the bowel wall with bacteria, usually gram-negative bacilli (especially *Pseudomonas*), with little or no surrounding inflammation, and progression to necrosis in some areas. In a review of 24 cases of typhlitis over 30 years, bacteremia was documented in 8 of 24 children, and thickening of the bowel wall was present on CT scans in 17 of 20 patients studied.[81] Most patients with typhlitis respond to medical management, including complete bowel rest, parenteral nutrition, broad-spectrum antibiotic therapy, and recovery from effects of cancer therapies, including resolution of neutropenia.[98] No controlled trials have evaluated optimal antibiotic therapy for typhlitis; empiric therapy should include agents active against enteric gram-negative bacteria and *Pseudomonas*, enterococci, and anaerobes. In patients with protracted fever despite broad-spectrum antibiotics, the addition of an antifungal agent is prudent. Surgical resection of necrotic bowel can be necessary when perforation, abscess formation, uncontrolled bleeding, or necrosis occurs.[99] In adults with neutropenic enterocolitis, mortality rates can exceed 50%.[100]

Clostridium septicum Infection.

Although uncommon, a catastrophic complication of typhlitis consists of spontaneous peritonitis and septicemia caused by *Clostridium septicum.* Neutrophil dysfunction and bowel ischemia are factors associated with increased risk and severity with *C. septicum* infection.[101] Peritonitis classically manifests fulminantly with rapidly progressive abdominal wall myonecrosis, crepitance, hemolysis, and shock; fever can be absent. *C. septicum* can be part of the natural flora of the gastrointestinal tract, is more aerotolerant than *Clostridium perfringens*, and can grow in viable, non-necrotic tissue. More than 80% of patients with *C. septicum* septicemia have an underlying malignant disease.[102,103] The steps in pathogenesis are thought to be loss of mucosal integrity secondary to malignant disease or chemotherapy, microbial invasion of the bowel wall, and rapid proliferation in the setting of immunosuppression or granulocytopenia.[104] Additionally, *C. septicum* produces an α toxin that may play some role in the severity of infection. Antibiotics with anticlostridial activity must be initiated urgently if *C. septicum* infection is suspected.

Hepatosplenic candidiasis.

Hepatosplenic candidiasis (also referred to as chronic disseminated candidiasis) is an invasive form of candidiasis that occurs in patients with cancer, especially patients with prolonged neutropenia. Clinical clues are persistent fever during neutropenia that is unresponsive to broad-spectrum antibiotics and, sometimes, right upper quadrant abdominal pain or tenderness and an elevated serum alkaline phosphatase level. Hepatosplenic candidiasis can occur despite antifungal therapy. Most often, multiple cultures from blood, urine, and other sites are sterile. Typical hepatic “bull's eye” lesions noted on ultrasonography or hypodense lesions can be seen as the neutrophil count begins to recover. Magnetic resonance imaging may be the most sensitive study. Before recovery of the inflammatory response, hepatic lesions can be missed by all imaging techniques available. The detection of *Candida* enolase antigen and d-arabinitol and mannan antibodies in serum has been used as an additional tool for diagnosing invasive candidiasis.[105–107] Confirmation of the diagnosis can require liver biopsy. Treatment usually requires a prolonged course of antifungal therapy.[108] Amphotericin B lipid complex has been shown to be effective in the treatment of hepatosplenic candidiasis.[109] Fluconazole has been used as salvage therapy in patients in whom amphotericin B treatment failed or who had serious amphotericin B–related toxicities, or as step-down oral therapy in improved patients.[31,52,110,111] Treatment failures with fluconazole in this setting, however, have been reported. Determining the appropriate end point of antifungal therapy is challenging, often depending on resolution or calcification of visualized lesions; antifungal therapy should be continued through periods of chemotherapy-induced immunosuppression.

Perianal Cellulitis

Although, in general, children have fewer chemotherapy-related perirectal lesions than do adults, children are prone to develop mucositis involving the rectal mucosa. These lesions provide a focus for local cellulitis or abscess, usually involving enteric gram-negative facultative and anaerobic organisms. Multiple organisms, most commonly anaerobes, are identified in most cases in which surgical drainage or needle aspiration is performed.[112] Most patients can be treated effectively with antibiotics alone. Appropriate choices include piperacillin-tazobactam, meropenem, or a fourth-generation cephalosporin, in combination with metronidazole.

Central Nervous System Infections

Infections of the CNS occur infrequently in children undergoing chemotherapy for cancer. These infections must be considered in children who have had a neurosurgical procedure. Placement of an intraventricular shunt poses an additional risk of infection; 25% of children experience a related CNS infection, but death is rare.[113] Indolent infections are most common with organisms of low pathogenicity, such as *Staphylococcus epidermidis* and *Propionibacterium acnes*; many shunt-associated infections can be resolved without removing the device. Because of the vague nature of associated symptoms, any child with a CNS device who has fever and no localizing findings should have cerebrospinal fluid sampled for cell count, chemical evaluation, and culture.

Although meningitis in patients with cancer is uncommon (one study noted that less than 0.9% of febrile neutropenic episodes in pediatric patients with cancer were caused by CNS infections[114]), but it is associated with significant mortality and morbidity rates.[115] Patients with fever and a change in mental status should be evaluated, diagnostic tests should be performed, and empiric therapy should be initiated promptly. Some studies have reported meningeal signs only in a minority of neutropenic patients or in patients who have had neurosurgical manipulation who develop meningitis[116–118]; thus the absence of meningeal signs does not exclude the diagnosis of meningitis. In a retrospective review of 40 cases of bacterial or fungal meningitis in pediatric patients with cancer, most patients (65%) had had recent neurosurgical procedures, a CNS device placed, or a cerebrospinal fluid leak, and one third of patients had neutropenia.[115] Fever and altered mental status were the most consistent signs; meningismus was notably less frequent in neutropenic patients. *S. aureus* and *S. pneumoniae* were the most common pathogens. Of the 5 patients with fatal outcomes, all were neutropenic at presentation. Candidal meningitis in children with cancer is rare but has high mortality rates.[119] Similarly, although the incidence of CNS *Aspergillus* infection is low, the mortality rate approaches 100%. A retrospective review of 81 adults with definite or probable CNS aspergillosis who were treated with voriconazole showed complete or partial response in approximately one third, as well as improved survival rates in patients who underwent therapeutic neurosurgical procedures.[120] In published data in children, CNS aspergillosis commonly manifested as brain abscesses, and as in adults, surgical management was associated independently with improved survival rates.[121,122]

Cystitis

Hemorrhagic cystitis, manifesting as bladder pain and significant gross hematuria, has been reported in bone marrow transplant recipients. Adenovirus (particularly type 11), CMV, and polyomavirus (BK virus) are causative agents. PCR detection of viruses is possible in both urine and blood.[123] Older age, receipt of HCT, and detection of BK virus were associated with risk of hemorrhagic cystitis and greater disease severity in children.[124] Although case reports documenting successful treatment of adenovirus and polyomavirus hemorrhagic cystitis with intravenous ribavirin, vidarabine, cidofovir, and ganciclovir have been reported, case-controlled randomized studies have not been performed to confirm benefit.[125–128]

Osteoarticular Infections

Bone and joint infections occurring in patients with cancer also are relatively rare. Children with soft tissue or bone tumors are at risk of infectious complications related to surgical tissue trauma or to destruction by the tumor. It can be difficult to distinguish osteomyelitis from tumor or the effects of local radiation. Any organism that can lead to bacteremia or fungemia (e.g., *Aspergillus* spp.,[129]) can cause osteomyelitis or arthritis. Diagnosis and treatment can be particularly complex in children who have had limb-sparing procedures involving bone and joint prostheses and whose longterm stability of the prosthesis is of concern. Serial imaging studies can suggest infection, but biopsy and culture of the involved bone are necessary for definitive diagnosis. Longterm antimicrobial therapy is mandatory when infection occurs, and revision of the prosthesis often is required for cure.[130]

Q

Infections Associated With Hospitalization and Medical Devices

OUTLINE

99 Healthcare-Associated Infections
100 Clinical Syndromes of Device-Associated Infections

99

Healthcare-Associated Infections

Jane M. Gould, Susan E. Coffin

A *healthcare-associated infection (HAI)* is defined as any infection not present or incubating at the time of the patient's initial contact with a healthcare setting. Originally termed *nosocomial, hospital-acquired,* or *hospital-onset infections,* the scope of HAI has expanded because patients now receive medical care in a wide variety of healthcare settings. Many HAIs are preventable and thus should be targeted for aggressive infection prevention programs (see Chapter 2). In 1985, the Study on the Efficacy of Nosocomial Infection Control (SENIC) project found that 5.7% of 169,526 patients hospitalized in 338 randomly selected US hospitals had an infection.[1] This group of investigators estimated that 32% of these hospital-onset infections could have been averted by the application of known principles and practices of infection prevention. We now know that most HAIs are preventable. Marked reductions in the rates of central line–associated bloodstream infections (CLABSIs), ventilator-associated pneumonia (VAP), and surgical site infections (SSIs) have been achieved through meticulous adherence to evidence-based practices.[2–6]

HAIs are common in children[7,8] (Tables 99.1 and 99.2). Rates, sites of infection, and microbiologic features of pediatric HAIs differ from those of HAIs in adults. Although children are less likely to have comorbid conditions that increase the risk of specific device-associated HAIs, they have greater risk of acquiring nosocomial viral infections because of the large reservoir of easily transmissible viruses in sites where children receive medical care. Bloodstream infections (BSIs) are the most common HAIs in children, whereas catheter-related urinary tract infections predominate in adults.[8] Rates of HAI in children vary by birth weight, age, underlying diseases, and intensity of medical care. Rates are highest in children <1 year of age and in children who require intensive care, especially in neonatal intensive care units (NICUs).[9–13] Risk factors in these patients are similar to those that predispose older patients to infections, such as severe underlying illness, loss of skin and mucosal barrier integrity, or the presence of multiple medical devices that breach normal defense mechanisms. Multidrug-resistant organisms are becoming more prevalent as causes of HAIs in both adult and pediatric populations. Of hospitals reporting to the National Healthcare Safety Network (NHSN) during the 2-year period from 2009 through 2010, approximately 20% of all HAIs were caused by multidrug-resistant organisms.[5] In a study matching patients infected with the same organism, antimicrobial resistance in both HAIs and community-associated infections was associated with higher charges, longer hospitalizations, and increased death rates.[14]

TABLE 99.1

Distribution of Pathogens by Infection Type Reported to the National Healthcare Safety Network, 2009 to 2010[a]

Pathogen	Number of Infections	Percentage (%)
CENTRAL LINE–ASSOCIATED BLOODSTREAM INFECTION		
Coagulase-negative staphylococci	6245	20.5
Enterococcus spp.	5501	18.1
Candida spp.	4439	14.6
Staphylococcus aureus	3735	12.3
Klebsiella pneumoniae/oytoca	2407	7.9
Enterobacter spp.	1365	4.5
Escherichia coli	1206	4
Pseudomonas aeruginosa	1166	3.8
VENTILATOR-ASSOCIATED PNEUMONIA		
S. aureus	2043	24.1
P. aeruginosa	1408	16.6
K. pneumoniae/oxytoca	854	10.1
Enterobacter spp.	727	8.6
Acinetobacter baumannii	557	6.6
Escherichia coli	504	5.9
CATHETER-ASSOCIATED URINARY TRACT INFECTION		

Escherichia coli	5660	26.8
Enterococcus spp.	3183	15.1
Candida spp.	2698	12.7
P. aeruginosa	2381	11.3
K. pneumoniae/oxytoca	2365	11.2

[a]Data include pathogens reported from adult and pediatric patients.

TABLE 99.2

Rates of Pediatric Healthcare-Associated Infections by Site in Hospital, From the National Healthcare Safety Network, 2013

Infection Type and Hospital Site	Pooled Mean[a]	Median (25%, 75%)[a]	Device Use[b]
CENTRAL LINE–ASSOCIATED BLOODSTREAM INFECTION			
PICU (medical/surgical)	1.2	0.7 (0, 1.7)	0.45
Pediatric CICU	1.3	1.2 (0.5, 2.0)	0.72
Pediatric inpatient unit	1.1	0 (0, 1.5)	0.20
Pediatric hematology/oncology unit	2.1	0.7 (0, 3.1)	0.20
Level III NICU (by birth weight):			
≤750 g	2.1	1 (0, 3.5)	0.39
751–1000 g	1.3	0 (0, 1.9)	0.33
1001–1500 g	0.8	0 (0, 0.9)	0.26
1501–2500 g	0.6	0 (0, 0)	0.17
≥2500 g	0.7	0 (0, 0)	0.23
CATHETER-ASSOCIATED URINARY TRACT INFECTION			
PICU (medical/surgical)	2.5	1.4 (0, 3.6)	0.21
Pediatric CICU	1.2	0.5 (0, 1.6)	0.21
Pediatric inpatient unit	3.4	0 (0, 5.0)	0.16
VENTILATOR-ASSOCIATED PNEUMONIA			
PICU (medical/surgical)	0.7	0 (0, 0.8)	0.37
Pediatric CICU	0.4	NA	0.39
Level III NICU (by birth weight):			
≤750 g	1	0 (0, 1.5)	0.38
751–1000 g	1.1	0 (0, 0)	0.22
1001–1500 g	0.7	0 (0, 0)	0.10
1501–2500 g	0.5	0 (0, 0)	0.06
≥2500 g	0.1	0 (0, 0)	0.1

[a]Rate of device-related infection per 1000 device-days.

[b]Device use = number of device-patient days / number of total patient days × 100.

CICU, cardiac intensive care unit; NICU; neonatal intensive care unit; PICU, pediatric intensive care unit.

From Centers for Disease Control and Prevention, National Healthcare Safety Network. Annual Report, 2013. http://www.cdc.gov/nhsn/datastat/index.html.

The NHSN, which is the most widely recognized source of US national data on hospital infections, is coordinated by the Centers for Disease Control and Prevention (CDC). Definitions of select neonatal HAIs are included, as are unique clinical manifestations in young children. Criteria for definitions of pneumonia and BSI are aged based: for patients ≤12 months and >12 months of age.[15] Because the NHSN provides HAI definitions and standard surveillance protocols, NHSN data are used commonly for benchmarking purposes.[16–18] Investigators have demonstrated repeatedly that significant differences in the application of standardized HAI definitions can undermine their valid use for interinstitutional comparisons.[19,20]

Bloodstream Infections

Device-Associated Infections

BSIs are the most common HAIs (see Table 99.1).[8] Among hospitalized and chronically ill patients, most CLABSIs and non-CLABSIs are related to the use of intravascular catheters. (see Chapter 100). In addition, pediatric patients are at risk for BSIs as a result of contaminated intravenous fluids or medications, blood or blood products, or dissemination from a distant site of infection.

Infections Associated With the Transfusion of Blood and Blood Products

Epidemiology and Pathogenesis.

The overall rate of infectious complications of blood transfusions is unknown, with estimated rates of contamination by bacteria, viruses, and protozoa varying substantially. The rate of bacterial contamination is estimated at 1 per 500,000 units of red blood cells and 1 per 10,200 units of random-donor platelets.[21] Use of apheresis platelets reduces the risk of transfusion-associated sepsis resulting from platelet contamination. In addition, blood transfusion is an independent risk factor for a variety of HAIs.[22] Although all fatalities associated with the transfusion of blood and blood products must be reported by law to the US Food and Drug Administration (FDA), some fatalities associated with transfusions can go unrecognized.

Although relatively rare, a wide variety of pathogens can be transmitted by blood transfusion. (Table 99.3). At present, the American Red Cross Blood Services screens each donor for risk of transmissible disease by questionnaire. Additionally, each unit of donated blood undergoes the following tests: rapid plasma reagin antibody for syphilis; surface antigen and core antibody for hepatitis B virus (HBV); nucleic acid amplification test for HBV DNA (since 2009), HIV-1 RNA (since 1999), HCV RNA (since 1999) and West Nile virus RNA (since 2003); antibody to hepatitis C virus (HCV); antibody to HIV types 1 and 2; antibody to human T-lymphotropic virus (HTLV) types 1 and 2; and enzyme immunoassay for *Trypanosoma cruzi* (Chagas disease) (since 2007).[23–26] Selective screening is performed in at-risk geographic areas for pathogens such as Dengue virus and *Babesia microti*. Since the introduction of screening for bloodborne pathogens and active education programs to pre-screen potential donors, the risk of infection is extremely low: 1 in 1,000,000 donations for HBV, 1 in 2,135,000 donations for HIV, 1 in 1,930,000 donations for HCV infection.[27,28] At present, the combined risk of transfusion-related infection with HIV-1, HIV-2, HTLV-1, HTLV-2, HBV or HCV is lower than the risk of a transfusion-related bacterial infection.[29,27,28]

TABLE 99.3

Predominant Infectious Agents Associated With Specific Blood Products

Blood Component	Storage Conditions	Predominant Organisms
Red blood cells	1°–6°C for 35–42 days	*Yersinia enterocolitica* *Pseudomonas* spp.
		Other gram-negative organisms
		Staphylococcus spp. *Propionibacterium* spp.
Platelets	20°–24°C for 5 days	*Staphylococcus* spp.
		Diphtheroids
		Bacillus spp.
		Salmonella spp. *Serratia* spp.
		Escherichia coli
		Enterococcus spp.
		Flavobacterium spp.
		Streptococcus spp.
Whole blood	1°–6°C for 35–42 days	Skin organisms, gram-negative organisms
Plasma	−18°C; thawed, 1°–6°C for ≥24 hr	*Staphylococcus* spp. *Propionibacterium* spp. *Pseudomonas aeruginosa*

Almost all reported acute infectious complications and most fatalities associated with the transfusion of blood products are due to bacterial pathogens. The manner in which a blood product is obtained, processed, and stored is a major determinant of pathogens transmitted.[30] For example, *Yersinia enterocolitica* and *Pseudomonas* species are associated with cold storage of red blood cells, while skin flora and gram-negative bacilli are more associated with whole blood and platelet transfusions (see Table 99.3). The FDA and the AABB (originally known as the American Association of Blood Banks) dictate the safe storage and handling of various blood products.[21] Various additional sources for contamination of blood and blood products have been identified, including the donor, equipment used to obtain and process the blood product, and procedures used for blood product administration. The FDA approved 3 new pathogen-reduction technologies capable of inactivating pathogens in donated blood components (i.e., platelets and plasma). Additional tests of whole blood and red blood cells are in phase II and III studies, which, if implemented, would further improve the safety of the blood component transfusion.[31]

Clinical Manifestations and Management.

Signs and symptoms associated with the transfusion of contaminated blood or blood products vary according to the characteristics and concentration of the microorganism and the severity of the recipient's underlying illness and immunologic compromise. Signs and symptoms of transfusion-related BSI range from mild fever to overwhelming septicemia with endotoxic shock.

In a patient who is receiving or has recently received (usually within 2 hours) a transfusion, the sudden onset of high fever and chills should raise the suspicion of transfusion-associated BSI. The transfusion must be discontinued immediately; the blood product should be examined visually for abnormalities such as hemolysis, clumping, and discoloration, and the residual blood product and the administration set should be refrigerated for further testing. Culture-confirmed episodes of transfusion-associated septicemia should be reported to the FDA Center for Biologics Evaluation and Research (301-827-6220; e-mail: fatalities2@cber.fda.gov).

Prevention.

Donor self-deferral and appropriate screening are essential to identify and exclude donors with potentially transmissible diseases.[30] Screening consists of a full history of recent illnesses and travel, as well as serologic and nucleic acid amplification test screening of donor blood. Despite laboratory-based screening, donors with asymptomatic or incubating infections can be missed. To enhance the safety of transfused blood, potential blood donors are asked to defer donation if they are known or suspected to have infection with West Nile virus or have recently returned from an area where malaria is endemic. Blood donation also is prohibited by people with a history of babesiosis or Chagas disease or people at risk of Creutzfeldt-Jakob disease or variant Creutzfeldt-Jakob disease.[32]

Meticulous aseptic technique must be used when performing venipuncture to avoid transfusion-related BSI resulting from skin flora. Contamination can occur from introduction of bacteria during blood collection or through withdrawal of a skin plug during venipuncture.[33,34] Even with appropriate skin antisepsis, skin plugs can harbor normal skin flora that could proliferate (especially in platelet concentrates stored at room temperature). Use of contaminated equipment during the collection or processing of blood also can lead to transfusion-associated infections.[35–37]

Respiratory Tract Infections

Epidemiology and Pathogenesis

Various healthcare-associated respiratory tract infections threaten hospitalized children, including pneumonia secondary to aspiration and VAP. Absence of preexisting immunity, an abundant reservoir of viruses in pediatric facilities and units, and children's behaviors and caretaking needs contribute to the increased risk of viral respiratory tract infection among children compared with adults. A nasopharyngeal or nasogastric tube can interfere with normal drainage of the sinuses and the eustachian tubes,[38,39] and these devices have been associated with healthcare-associated sinusitis and otitis media.[40,41]

Pneumonia.

The CDC estimated that 157,500 cases of healthcare-associated pneumonia occurred in acute care hospitals in the United States in 2011.[42] Overall, pneumonia and SSIs were the most common HAIs, each representing 21.8% of the total HAI burden as identified by the CDC Emerging Infections Program.[43,44] The NHSN data summary for 2013 reported that VAP was the third most prevalent device-associated infection in children and that VAP occurred more frequently in the neonatal population.[8] VAP is associated with increased morbidity and hospital costs.[45] The attributable mortality rate of VAP is estimated to be approximately 10% in adults.[46–48] Data from pediatric populations are more limited, but mortality rates appear to be lower in children; however, multivariate analyses of predictors of death have not been performed in children with VAP.[49–51]

Aspiration Pneumonia.

Although bacterial pneumonia can occur through hematogenous spread or aerosolization, most cases result from aspiration of bacteria that colonize the upper airway or gastric mucosa of a hospitalized or chronically ill patient.[52–55] Although the most common source of organisms is controversial, studies of ventilated patients have shown that enteric and gram-positive organisms begin to colonize these areas within hours of intubation.[52,55] Microaspiration of bacteria into the trachea is hypothesized to be a primary mode of pathogenesis.[56] Risk factors for aspiration include preexisting neurologic or neuromuscular conditions, decreased gastric motility, placement of an endotracheal tube, and sedation, which can lead to pooling of oral secretions.[57,58] When oropharyngeal secretions carrying pathogenic bacteria are aspirated into the lower airway, a polymicrobial pneumonia can ensue. In contrast, a noninfectious chemical pneumonitis can follow aspiration of gastric secretions; it typically has a more rapid onset (e.g., within 6 hours of aspiration) and often is not accompanied by fever.[59] Nonetheless, differentiation of bacterial from chemical causes of lower respiratory tract disease can be difficult.

Ventilator-Associated Pneumonia.

The epidemiology of VAP is well described in adults, but few data exist for pediatric patients, who appear to have a lower incidence of VAP. Pathogenesis of VAP in adults and children presumably is similar. Alterations in the glycoprotein fibronectin, which coats the respiratory epithelium, can occur within hours of hospitalization and can enhance the adherence of gram-negative bacilli to the respiratory mucosa.[60–62] An endotracheal or nasotracheal tube provides the conduit by which organisms colonizing the oropharynx or nasopharynx migrate to the lower respiratory tract. Artificial airway devices also inhibit host defenses such as the gag reflex and ciliary function, and they provide a substrate for the formation of biofilms.[52,55] Biofilms, another reservoir of pathogenic bacteria, can be dislodged through mechanical suctioning or high-pressure airflow and delivered directly to the lower respiratory tract. Mechanical ventilation also has been shown in animals to increase toll-like receptor 3–mediated lung inflammation and permeability.[63]

Bacteria that cause VAP also can arise from aspirated material from the digestive tract. A study of adults in intensive care units (ICUs) found significantly higher levels of total bile acids in oral secretions of patients with VAP compared with control subjects, a finding suggesting that gastroesophageal reflux can play a role in the development of VAP.[64] At normal pH (1–2), the gastric mucosa does not support the growth of bacteria that typically cause VAP. However, use of proton-pump inhibitors and histamine type 2 (H_2)–receptor antagonists for prophylaxis against stress ulcer promotes changes in the colonization of the upper gastrointestinal tract. Studies of critically ill adults have shown repeatedly that patients receiving such prophylactic agents have a higher rate of VAP than do patients who receive the cytoprotective agent sucralfate.[65,66] Thus the risk of pneumonia must be balanced against the risk of clinically significant gastrointestinal bleeding.

Risk factors for VAP in children also include the presence of a genetic syndrome, reintubation, neuromuscular blockade, and immunosuppression.[49] The risk of VAP in neonates increases with decreasing postconceptual age, antecedent BSI, and increasing duration of intubation.[12,67,68]

Pseudomonas aeruginosa and methicillin-resistant *Staphylococcus aureus* (MRSA) are the most common organisms recovered from critically ill children with VAP.[13,49,69,70] NICU patients also have a risk of VAP caused by *Enterococcus* (group B *Streptococcus*) and methicillin-susceptible *S. aureus* (MSSA).[68] Respiratory viruses have been recovered from the lower respiratory tract in children with VAP in the absence of other pathogens.

Viral Respiratory Tract Infections.

Viruses are the most common causes of healthcare-associated upper and lower respiratory tract infections in children. Most nosocomial viral infections have exogenous sources (e.g., from family members or other visitors), occur during community outbreaks, and have the potential for widespread transmission within healthcare settings.[71–73] The hospital environment can become contaminated with respiratory viruses that can persist on inanimate surfaces. Factors such as visitation (especially of young siblings), playroom use, reluctance by ill healthcare personnel (HCP) to use sick leave, and low influenza vaccination rates among HCP contribute to an increased burden of viral HAIs. A survey of advanced-practice clinicians and physicians at a children's hospital revealed knowledge that working while ill put their patients at risk, but most HCP worked while ill (for a variety of reasons). The most common symptoms of HCP working while ill were respiratory, but 30% of HCP who worked while ill reported diarrhea, and 16% reported fever.[74]

Both children with underlying conditions and acutely ill patients are at risk for viral pneumonia.[65] Many viruses, including adenovirus, influenza virus, measles virus, parainfluenza virus, respiratory syncytial virus (RSV), human metapneumovirus, rhinoviruses, and varicella-zoster virus, can cause healthcare-associated pneumonia. Among viral respiratory tract pathogens, the modes of transmission of RSV have been studied most carefully.[71,75–77] Both droplet transmission from close contact with infectious people and indirect contact transmission through hands or fomites contaminated by secretions occur during hospital-based outbreaks, RSV-contaminated hands probably are the predominant means of cross-infection.[78,79] Other respiratory viruses, such as influenza virus, most often are transmitted by respiratory droplets. However, the possible role of airborne transmission of influenza has led to newer recommendations for the use of enhanced respiratory protection and environmental controls when performing aerosol-generating procedures on patients with known or suspected influenza virus infection.[80]

Clinical Manifestations and Laboratory Diagnosis

Ventilator-Associated Pneumonia.

VAP is difficult to confirm. The classic findings associated with lower respiratory tract infection (fever, cough, production of purulent sputum, and a new or progressive pulmonary infiltrate on chest radiographs) are not present consistently or can represent another process, such as atelectasis or acute respiratory distress syndrome.[81] The NHSN developed guidelines for the diagnosis of VAP in pediatric patients based on clinical and radiographic criteria; the sensitivity and specificity of these criteria are poor.[82–86] Because of the inherent subjectivity associated with elements of the VAP diagnostic criteria, the NHSN implemented a surveillance definition for adult *ventilator-associated events* (VAE) in 2013 that uses objective criteria and expands the focus of surveillance to include additional complications of mechanical ventilation, both infectious and noninfectious. VAE includes ventilator-associated condition (VAC), defined by respiratory deterioration after a period of stability while the patient is being mechanically ventilated; and infection-related ventilator-associated complication (iVAC), a subset of which can be VAP. CDC studies addressing performance of these definitions in pediatrics are ongoing, but preliminary data suggest that pediatric patients, including neonates with VAC, have higher risks of morbidity and death regardless of ventilatory thresholds (fraction of inspired oxygen and mean airway pressure) used.[87]

According to the NHSN, VAP should be considered when pneumonia develops in a patient who has received mechanical ventilation for >2 calendar days (with day of ventilator placement being day 1, and the ventilator being used 1 day before or on the day of the event). If the patient is admitted or transferred into a facility while he or she is on a ventilator, the day of admission is considered day 1. Currently, 3 NHSN pneumonia definitions (PNU1, PNU2, and PNU3) exist, according to the microbial origin of the infection or the immune status of the intubated patient. Each definition requires compatible signs and symptoms of lower respiratory infection, imaging findings, and laboratory evidence of infection. PNU1 is further differentiated by the age of the patient.[83] Accurate diagnosis is more likely when specimens are obtained by bronchoscopy, lung biopsy, lung aspiration, protected-specimen brush technique (whether bronchoscopic or nonbronchoscopic), or transtracheal aspiration rather than by aspiration of tracheal contents through an endotracheal tube.[84–88] The isolation of potentially pathogenic bacteria from such specimens does not confirm VAP because recovery of bacteria could represent lung colonization or infection at another site (e.g., sinusitis or tracheobronchitis). The use of clinical criteria in addition to positive sputum or tracheal culture results has low specificity for VAP.[89,90] Advances in the diagnosis of VAP in adults have included the use of bronchoalveolar lavage or protected sample brush to obtain secretions of the lower respiratory tract for quantitative culture. However, these procedures are not used routinely in children because of technical difficulties and the potential for complications. In NICU patients, it is difficult to obtain any specimen through the endotracheal tube other than suctioned secretions. In a study comparing diagnostic methods in children, quantitative culture of lower respiratory tract secretions obtained by blind, protected bronchoalveolar lavage was the most reliable diagnostic test; a bacterial index (the sum of the $\log_{10}$ of all species obtained by bronchoalveolar lavage) of >5 was predictive of VAP.[81]

The Clinical Pulmonary Infection Score (CPIS), a tool used to identify adult ICU patients with pulmonary infection, demonstrated good correlation and subsequently was modified and evaluated as a tool to limit unnecessary antibiotic use in an adult ICU. Patients found to be at low risk for infection by the modified CPIS were managed successfully with a short course of empiric antibiotic therapy.[91] Additionally, use of the modified CPIS resulted in significantly lower antimicrobial therapy costs and antibiotic resistance, without adversely affecting patients' mortality rates and lengths of ICU stay. Clinical scoring systems to establish a diagnosis of bacterial pulmonary infection have not been validated in pediatrics. Many children with presumed VAP may not have significant bacterial infections.

Viral and Other Respiratory Tract Infections.

The accurate diagnosis of healthcare-associated (HA) viral respiratory tract infections relies on the availability of certain viral diagnostic procedures. Although few antiviral therapies exist, accurate diagnosis can uncover a problem, permit prompt infection prevention measures to reduce widespread transmission, and reduce unnecessary use of antibiotics.[92,93] Detection of virus (by culture), viral antigen (by immunoassays), or viral genome (by polymerase chain reaction [PCR]) in a specimen obtained from the respiratory tract, combined with clinical and radiographic findings consistent with lower respiratory tract infection, generally is accepted as confirmation of viral pneumonia.[83] For viruses that can be shed for prolonged periods (e.g., bocavirus, rhinoviruses, and some adenoviruses) or are latent and can reactivate (e.g., herpes simplex virus or cytomegalovirus), confirmation of a causal role is more difficult and can require histologic examination of tissue or demonstration of increasing viral load determined by quantitative PCR. The NHSN definition of viral pneumonia and of *Legionella* and other bacterial pneumonias (PNU2) includes imaging evidence in addition to signs and symptoms compatible with pneumonia (as described earlier) and laboratory evidence by at least one of the following means: culture of virus, *Legionella,* or *Chlamydophila* from respiratory secretions; nonculture diagnostic tests of secretions or tissue for virus, *Bordetella*, *Chlamydophila*, *Mycoplasma*, or *Legionella* spp. (e.g., enzyme immunoassay, shell vial assay, PCR); a fourfold rise in pathogen anti–immunoglobulin G in paired acute and convalescent sera; or detection of *Legionella pneumophila* serogroup 1 antigen in urine by radioimmunoassay or enzyme immunoassay.[83]

Management and Outcome

Ventilator-Associated Pneumonia.

Empiric management of suspected bacterial pneumonia depends on both patient-specific and hospital-related considerations. All of the following should be considered: the patient's underlying disease, previous antimicrobial therapy, mental status (and other conditions that increase the risk of aspiration), and length of hospitalization; the results of Gram stain examination of respiratory tract specimens; and detailed knowledge of the hospital's antibiogram for bacterial pathogens derived from microbiologic surveillance data.

Empiric treatment for VAP generally is given when a new infiltrate is visualized on chest radiographs in association with fever, an increase in quantity or purulence of respiratory tract secretions, a rising neutrophil count, or an unexplained decrease in oxygen saturation. Gram stain and culture of respiratory tract secretions commonly are used to support the diagnosis. Guidelines for the treatment of adults with HA pneumonia and VAP are available from the Infectious Diseases Society of America,[94] but many of the principles likely apply well to children.

The outcome of HA pneumonia varies by the characteristics of both the patient and the pathogen. VAP is associated with significant morbidity and death, particularly in neonates; the case-fatality rate for neonates is reported to be 10%, and extremely premature infants have a fatality rate of 27%. Among pediatric ICU (PICU) patients, the reported fatality rate is approximately 6%. VAP is associated with prolonged ICU and hospital stay in both NICU and PICU patients.[49] Because delays in the initiation of appropriate therapy have been associated with increased morbidity and mortality rates,[95,96] empiric therapy should be broad based. Negative results of lower respiratory tract cultures from specimens taken before a recent change in antibiotic therapy can be used to discontinue empiric therapy. Microbiologic results of respiratory cultures should be used to narrow antibiotic therapy. Short courses (5–7 days) of appropriate antibiotic therapy may be adequate in patients with uncomplicated VAP who have a good initial clinical response to treatment.[97]

Viral Respiratory Tract Infections.

Children with HA influenza virus infection should receive age-appropriate antiviral therapy, ideally within 48 hours of symptom onset. Data on hospitalized patients who show improved outcomes related to antiviral therapy are limited.

Although ribavirin has in vitro activity against RSV, ribavirin generally is not given for uncomplicated RSV infection.[98,99] Clinical improvement achieved during aerosolized ribavirin administration in studies has been limited or sometimes insignificant. Several studies reported therapy-associated clinical improvement and subsequent reductions in length of mechanical ventilator support;

however, findings have varied.[99,100] Treatment may be prudent in selected patients, such as patients with hemodynamically significant congenital heart disease, profound immunocompromise, or potentially life-threatening infection.

Immunotherapy with RSV monoclonal antibody has been evaluated for therapy; with no significant impact on hospital course.[101–103] RSV monoclonal antibody is not recommended or approved by the FDA for the treatment of RSV infection in any patient group.

Prevention.

The Society for Healthcare Epidemiology and the Infectious Diseases Society of America produced an evidence-based practice recommendation entitled "Strategies to Prevent Ventilator-Associated Pneumonia in Acute Care Hospitals: 2014 Update."[104] A summary of the recommendations to prevent VAP is shown in Box 99.1. Major areas for preventive interventions include avoiding aspiration, minimizing contamination of respiratory mucosa and equipment, and reducing the exposure to mechanical ventilation. Taken together, these interventions, sometimes called "bundles," can reduce the incidence of VAP substantially.[105–107]

Box 99.1

Prevention of Ventilator-Associated Pneumonia

General Strategies

- Conduct active surveillance for VAP.
- Pay careful attention to hand hygiene.
- Use noninvasive ventilation when possible.
- Minimize the duration of mechanical ventilation (assess extubation readiness daily in patients without contraindications).
- Interrupt sedation once a day.
- Educate staff on VAP prevention strategies.

Strategies to Prevent Aspiration

- Maintain patients in a semirecumbent position (30–45-degree elevation). Consider lateral recumbent or reverse Trendelenburg positioning in preterm neonates.
- Avoid gastric overdistention.
- Avoid unplanned extubations and reintubations.
- Use a cuffed endotracheal tube with in-line or subglottic suction. Suction oral secretions before each position change.

Strategies to Reduce Colonization of Respiratory Mucosa

- Perform regular oral care with an antiseptic solution or sterile water for preterm neonates.
- Avoid nasotracheal intubation when possible.
- Consider using alternative acid-suppressing therapy (e.g., sucralfate) in patients at low risk of gastrointestinal bleeding.
- Consider prophylactic probiotics.

Strategies to Minimize Contamination of Equipment

- Use sterile water to rinse reusable respiratory equipment.
- Drain condensate regularly, but keep circuit closed when removing condensate.
- Change circuit only when visibly soiled or malfunctioning.
- Store and disinfect respiratory therapy equipment properly.

VAP, ventilator-associated pneumonia.

Additional study is needed to define the optimal methods to prevent HA viral respiratory tract infection in children. Macartney and colleagues[79] demonstrated that a targeted, multicomponent program designed to reduce nosocomial transmission of RSV was effective and cost-efficient. Components include: (1) prompt laboratory confirmation of infection, (2) cohorting of patients and nursing staff, and (3) use of contact precautions (gloves and gowns). Little is known about the efficacy and cost-efficiency of similar programs targeted at other pathogens. Other institutional factors, such as appropriate use of HCP sick leave, consistent visitor screening or visitor restriction (either hospitalwide or in certain units during respiratory viral season or community outbreaks), and mandatory influenza vaccination of HCP, also are important strategies to prevent transmission of respiratory viruses in healthcare settings.

Gastrointestinal Tract Infections

Epidemiology and Pathogenesis

HA gastroenteritis is relatively common but frequently overlooked because many episodes resolve quickly without specific therapy.[108] Infants and older adults are at greatest risk; a point prevalence survey in multiple pediatric acute care hospitals estimated rates of HA gastroenteritis (viral gastroenteritis in addition to *Clostridium difficile* infection) from ~1% in neonates to 3.5% in school-aged children.[108] Several factors are affecting changes in the epidemiology of nosocomial gastroenteritis. The introduction of rotavirus vaccine has led to substantial reductions in community-onset infections and appears to be associated with similar reductions in nosocomial rotavirus infections.[109] The incidence of *C. difficile* colitis among hospitalized children has risen.[110–113] Norovirus has emerged as a commonly recognized cause of both community-onset gastroenteritis and HA gastroenteritis.[114,115]

Intrinsic factors heighten the risk of gastrointestinal infections in hospitalized patients, including impairment of immunity, alterations in gastric acidity, and changes in gastric motility and intestinal flora. Several studies have shown that hematopoietic cell transplant recipients and patients with severe immunodeficiencies are at risk of repeated and prolonged episodes of HA viral gastroenteritis and *C. difficile* gastroenteritis.[116–119] Furthermore, immunocompromised people excrete high density of viruses for prolonged periods and are important reservoirs within healthcare settings.[120]

Extrinsic factors also influence the risk of HA gastroenteritis, including adherence to hand hygiene practices, use of nasogastric tubes, and use of gastric acid–suppressing medications.[121] Indirect contact through fomites or environmental contamination plays a role in the transmission of *C. difficile* and norovirus, likely related to the relative resistance of these organisms to commonly used disinfectants. Contaminated foods or other common vehicles have been associated with the transmission of *Salmonella, Shigella, Yersinia enterocolitica, Escherichia coli,* noroviruses, and *Cryptosporidium* species.[122–126]

Viral Gastroenteritis.

Viruses are among the most common causes of HA gastroenteritis in children. Norovirus infections are increasingly recognized as the cause of both sporadic and outbreak-related cases of nosocomial gastroenteritis,[127–129] and they have surpassed declining rotavirus cases.[130–132] Noroviruses cause approximately two thirds of the identified HA outbreaks of gastroenteritis, likely related to ease of transmission by direct and indirect contact, including through food or water sources.[126,127,129,130,131] Environmental contamination frequently is implicated as a cause of protracted norovirus outbreaks.[132] Immediate cohorting of ill patients, furlough of ill HCP, and implementation of stringent environmental control measures are necessary to halt transmission.

Clostridium difficile Infection.

In both children and adults, *C. difficile* infection is the most important bacterial HA gastrointestinal disease. The epidemiology of *C. difficile* infection is complex in the pediatric population, with an unsettled role of this agent in gastroenteritis in infants and young children (see also Chapter 190).[133–135] Up to 50% of healthy neonates may be colonized with toxigenic forms of *C. difficile,*[136–138] and infants can be reservoirs for community-onset *C. difficile* infection among older children and adults.[139] After the age of 2 years, colonization rates decrease to adult levels of <5%, although colonization is substantially more prevalent in hospitalized patients with or without exposure to antimicrobial agents.[133,134]

Clinically apparent disease occurs when the microbial ecology of the gut is disrupted. *C. difficile* can proliferate and elaborate potent toxins A and B, which stimulate secretory diarrhea and inflammatory colitis.[140] Although a few cases of antibiotic-associated diarrhea and not all cases of pseudomembranous colitis are caused by *C. difficile*, *C. difficile* is the most commonly identified pathogen.[141] The major risk factors for HA *C. difficile* colitis in children are exposure to a wide variety of antimicrobial agents, underlying gastrointestinal disease (including the use of percutaneous feeding tubes), and immunocompromising conditions.[142–144]

Clinical Manifestations and Laboratory Diagnosis

Viral Gastroenteritis.

Rotavirus and norovirus typically cause noninflammatory diarrhea, often associated with fever and vomiting, that frequently leads to dehydration.[145] In immunocompetent children, symptoms typically resolve within 2 to 4 days. Norovirus and rotavirus are detectable in stool samples by PCR, and rotavirus can be identified by antigen detection assays. Other agents identified in children with HA gastroenteritis include sapovirus, adenovirus 40/41, and astrovirus.[115]

Clostridium difficile Gastroenteritis.

Symptoms of *C. difficile* infection typically begin 1 to 21 days (mean, 4 days) after initiation of antimicrobial therapy. However, occasionally symptoms begin after the drug is discontinued. Associated signs and symptoms include fever, cramping abdominal pain, distention, nausea, and vomiting. Typically, overt hematochezia does not occur, although stools frequently are foul smelling and can contain occult blood.[146] Severe disease occurs in 10% to 20% of patients with HA *C. difficile* infection and includes toxic megacolon, pneumatosis intestinalis, and intestinal perforation.[140,141,146–148] HA *C. difficile* infection has been associated with an almost sevenfold increased risk of death and prolonged hospital stay in children.[149]

Advances in diagnostic assays and improved algorithms for rejecting samples (formed stools) from patients unlikely to have *C. difficile* infection have improved the predictive value of diagnostic assays.[150,151] Two-step testing algorithms that include detection of *C. difficile* organisms by glutamate dehydrogenase assays coupled with more sensitive assays to detect *C. difficile* toxin (e.g., nucleic acid amplification tests) have excellent predictive values.[152,153] Occasionally, endoscopy is required for definitive diagnosis. Lesions in the colon or small bowel are red, edematous, and friable, with multiple raised, yellowish plaques (pseudomembranes) that consist of mucus, fibrin, necrotic cells, and polymorphonuclear cells.

Management, Outcome, and Control

Viral Gastroenteritis.

Viral gastroenteritis typically is self-limited. Supportive care with careful attention to hydration status remains the cornerstone of management.[154] Rotavirus and norovirus have been shown to contaminate the fomites and persist on inanimate objects for long periods.[155] Appropriate cohorting of patients and staff, use of contact precautions, and careful attention to hand hygiene and environmental cleaning are critical to preventing transmission.[132,156,157] Because norovirus and *C. difficile* spores are resistant to alcohol, many institutions use soap and water for hand hygiene when providing care for these patients. Some experts argue that appropriate use of standard precautions (including use of gloves) obviates the need for this practice divergence when only sporadic cases of infection occur. When a cluster of norovirus or *C. difficile* cases occurs, the use of soap and water for hand hygiene is advisable.

Clostridium difficile Infection.

First-line therapy for *C. difficile* infection is discontinuation of antibiotics whenever possible and supportive care. Oral metronidazole and vancomycin are effective therapies generally, although data in adults suggest that treatment with oral vancomycin is associated with improved clinical outcomes and lower rates of recurrence.[158] Similar studies have not been performed in children. Response to treatment generally occurs within 48 hours, but some patients may not have full resolution of diarrhea and other symptoms for up to 1 week after starting therapy.

Relapse after therapy occurs in up to 35% of patients and can reflect infection with a different strain, reinfection with the same organism (often from a persistent environmental reservoir), or relapse secondary to failure to eradicate the initial infection.[159,160] Host factors such as preexisting gastrointestinal disease, immunologic impairment, and repeated exposure to antimicrobial agents, as well as the severity of the initial episode, can affect the frequency.[160] A Cochrane meta-analysis concluded that "moderate quality evidence suggests that use of probiotic agents is safe and effective for preventing *C. difficile*-associated diarrhea" in adults and children[161]; however, adoption of this practice has not been universal.

Strict adherence to infection control practices is critical to prevent nosocomial transmission of *C. difficile* gastroenteritis. Contact isolation precautions should be instituted for any patient with symptomatic infection. Because *C. difficile* commonly contaminates the inanimate environment, care should be taken to use gloves appropriately and perform hand hygiene immediately on glove removal after any contact with the patient or the patient's environment.[162] One study demonstrated an increased risk of *C. difficile* among patients occupying a room that was previously occupied by an infected patient. Careful terminal environmental cleaning of patients' rooms with a sporocidal agent is essential.

Surgical Site Infections

Epidemiology and Pathogenesis

SSIs represent 14% to 16% of all infections reported to the NHSN.[18] Using a structured sampling strategy, investigators for the Pediatric National Surgery Quality Improvement Project calculated a standardized, risk-adjusted ratio of SSIs after >30,000 pediatric surgical procedures of 1.8% and noted the highest rate of SSIs following neurosurgical procedures (Table 99.4).[163] Specific pediatric SSIs, including mediastinitis, ventricular shunt infection, and infection after placement of orthopedic prostheses, are associated with substantial morbidity and have been targeted by several different improvement collaboratives.

TABLE 99.4

Rates of Surgical Site Infections for Specific Pediatric Specialties, American College of Surgeons National Surgical Quality Improvement Program, 2010

Specialty	Surgical Site Infection Rates (%)[a]	
	All Cases	Neonates
General surgery	3.8	6.2
Otolaryngology	1.1	0
Orthopedics	2.5	2.7
Urology	1.5	2.4
Neurosurgery	6.3	12.6
Plastic surgery	3.1	0

[a] Rates have been risk adjusted using the National Surgical Quality Improvement Program hierarchical model.

Development of an SSI requires a reservoir of microorganisms, a mode of transmission, and a suitable wound. Surgical infections usually result from intraoperative seeding of the site by the patient's own flora or by inoculation with exogenous bacteria (Table 99.5). At present, the relative contribution of postoperative factors (e.g., wound management) is understood poorly.[164]

TABLE 99.5

Microbiology of Postoperative Infections in Surgical Patients

Nature of Operation	Likely Pathogens (in Alphabetic Order)
"CLEAN" SURGERY[a]	
Cardiac[b]	
Prosthetic valve, coronary artery bypass, other open heart surgery, pacemaker implant	(CoNS, *Corynebacterium* spp., enteric gram-negative bacilli, *Staphylococcus aureus*
Vascular	
Arterial surgery involving the abdominal aorta,	CoNS, enteric gram-negative bacilli, *S. aureus*

a prosthesis, or a groin incision	
Lower extremity amputation for ischemia	CoNS, *Clostridium* spp., enteric gram-negative bacilli, *S. aureus*
Orthopedic	
Total joint replacement, internal fixation of fractures	CoNS, *S. aureus*
Ophthalmic	CoNS, enteric gram-negative bacilli, *Pseudomonas, S. aureus, Streptococcus* spp.
Head and Neck	
Incisions through oral cavity or pharynx	Anaerobic bacteria, enteric gram-negative bacilli, *S. aureus*
Craniotomy	CoNS, *S. aureus*
Abdominal	
Gastroduodenal[c]	Enteric gram-negative bacilli, gram-positive cocci
Biliary tract[d]	*Clostridium* spp., enteric gram-negative bacilli, *Enterococcus* spp.
Colorectal	Anaerobic bacteria, enteric gram-negative bacilli, *Enterococcus* spp.
Appendectomy, nonperforated	Anaerobes, enteric gram-negative bacilli, *Enterococcus* spp.
“DIRTY” SURGERY[e]	
Ruptured viscus	Anaerobes, enteric gram-negative bacilli, *Enterococcus* spp.
Traumatic wound[f]	*Clostridium* spp., group A *Streptococcus, S. aureus*

[a] Parenteral prophylactic antimicrobial agents can be given as a single intravenous dose just before the operation. For prolonged operations, additional intraoperative doses should be given every 4 hours for the duration of the procedure.

[b] An additional dose can be given after patients are removed from bypass during open heart operations.

[c] Morbid obesity, decreased gastric acidity, or decreased gastrointestinal motility.

[d] Acute cholecystitis, nonfunctioning gallbladder, obstructive jaundice, or common duct stones.

[e] For “dirty” surgical procedures, therapy usually should be continued for 5 to 10 days.

[f] For bite wounds, likely pathogens also can include oral anaerobic bacteria, *Eikenella corrodens* (human), and *Pasteurella multocida* (dog and cat).

CoNS, Coagulase-negative staphylococci.

Adapted from Bratzler DW, Dellinger EP, Olsen KM, et al. Clinical practice guidelines for antimicrobial prophylaxis in surgery. Am J Health Syst Pharm 2013;70:195–283.

The risk of an SSI is influenced strongly by both patient-related and procedure-related risk factors. Patient-related risk factors in children associated with SSIs include comorbid conditions (including genetic syndromes),[165–167] obesity,[168,169] and prematurity.[170,171] Race also may be an independent risk factor for SSIs, although further understanding and confirmation are needed.[172,173] Procedure-related factors include the type (clean vs.

clean-contaminated vs. dirty) and length of the surgical procedure,[17,174,175] appropriate use of perioperative antibiotics,[166,176,177] use of a medical device during the procedure,[171,172] and the presence of a remote infection.[178,179] Although evidence from pediatric studies is sparse, other risk factors associated with SSIs include immune status, method of preoperative hair removal,[180] and surgical technique.[181,182]

Cardiac Surgery.

Children who undergo surgical repair of congenital heart disease have a high risk of SSI. The incidence of superficial wound infections after median sternotomy is difficult to estimate because of the challenges differentiating normal wound healing from changes associated with early infection. Sternal osteomyelitis after median sternotomy is a rare but serious complication, often requiring reoperation for debridement and prolonged courses of antibiotics. The most serious infectious complication after pediatric cardiac operations is mediastinitis, with an estimated incidence ranging from 0.1% to 5%. Procedures performed in neonates or that involve delayed sternal closure have the highest reported rates of mediastinitis.[183,184] Factors independently associated with pediatric mediastinitis include young age, prolonged preoperative hospitalization, preoperative ventilator support, and genetic abnormalities.[184,185] Other risk factors for pediatric cardiac SSIs (including superficial infections, deep infections, and mediastinitis) include prolonged use of intracardiac pacing wires, previous operation, colonization with MRSA, and delayed sternal closure.[165,186–189]

Staphylococci are the predominant pathogens causing postoperative mediastinitis.[190] In children, *S. aureus* accounts for 38% to 96% and coagulase-negative staphylococci account for 10% to 52% of episodes of mediastinitis.[191–193] Gram-negative organisms and *Candida* spp. are less common, although a case series reported that gram-negative pathogens caused 30% of cases.[193,194]

Ventricular Shunt Placement.

Each year in the US, approximately 20,000 pediatric neurosurgical procedures are performed to place a shunt to drain cerebrospinal fluid (CSF). Substantial risk exists for both superficial and deep postoperative infections.[195] Because the proximal tip of the shunt catheter usually is placed within the ventricular cavity, SSIs often consist of localized ventriculitis (in children with obstructive hydrocephalus) or meningitis (in children with free circulation of CSF). Approximately 10% of newly placed CSF shunts become infected within 1 year, with an escalating risk with each subsequent CSF shunt procedure.[196] Additional risk factors include prematurity, shunt revision within 90 days, postoperative CSF leak, and intraoperative breach in aseptic technique.[197–199] Skin organisms such as *S. aureus* and *Staphylococcus epidermidis* are the most common causes of CSF shunt infections.[200,201] Infections with *Proprionibacterium spp.* can be particularly indolent and difficult to diagnose because of the fastidious nature of these organisms.

Spinal Fusion.

The risk of SSI after pediatric spinal fusion is highly associated with specific patient-related characteristics. Adolescents undergoing spinal fusion for idiopathic scoliosis a have 0.5% to 1.6% risk of SSI, whereas children with associated neurologic or neuromuscular conditions have an SSI risk of ≥20%.[167] Factors such as bowel incontinence, malnutrition, and a need for instrumentation that extends to the pelvis are thought to underlie a heightened risk.[202] The microbiology of SSI after spinal fusion also varies by patient-related factors. *S. aureus, S. epidermidis,* and *Propionibacterium acnes* are common causes of SSI in teens with idiopathic scoliosis, whereas gram-negative bacilli are more prevalent in children with nonidiopathic scoliosis.[167]

Clinical Manifestations and Laboratory Diagnosis

A surgical wound is not infected if it heals primarily without discharge. In contrast, a wound can be considered infected if purulent discharge develops, even if microorganisms are not recovered from culture of discharge fluid.

For surveillance purposes, the NHSN classifies SSIs into incisional infections and organ or space (i.e., involving the surgical bed or other tissues) infections. Incisional infections are subdivided into superficial (involving only the skin and subcutaneous tissue) and deep (involving fascia and muscle) categories.[18] By definition, a *superficial incisional SSI* must occur within 30 days of the operative procedure and meet at least one of the following criteria: (1) purulent fluid is draining from the incision; (2) an organism is isolated from an aseptically obtained wound culture; (3) a symptom such as pain, tenderness, localized swelling, redness, or heat induces the surgeon to open the incision; or (4) a diagnosis of infection is made by the surgeon.

By definition, a *deep incisional SSI* must occur within 30 days after most procedures, or within 90 days after selected procedures that include placement of a homograft or prosthetic material, and meet at least one of the following criteria: (1) purulent fluid is draining from the deep incision (but not from the organ or space component of the site); (2) the deep incision spontaneously dehisces or is opened by the surgeon when the patient has fever (>38°C), localized pain, or tenderness (unless the incision is culture negative); (3) an abscess or other evidence of infection is identified on direct examination, by an imaging study, or by histopathologic specimen examination.

An *organ or space infection* involves deeper spaces entered or manipulated during the operative procedure; examples are mediastinitis after surgical repair of complex congenital heart disease and osteomyelitis after laminectomy. By definition, an organ or space SSI must occur within 30 days after most procedures, or within 90 days after selected procedures that include placement of a homograft or prosthetic material, and meet at least one of the following criteria: (1) purulent fluid is emitting from a drain placed into the organ or space; (2) an organism is isolated from an aseptically obtained culture from the organ or space; (3) an abscess or other evidence of infection is identified on direct examination, by an imaging study, or by histopathologic specimen examination.

Cardiac Surgery.

Common signs and symptoms of postoperative mediastinitis include local tenderness, wound dehiscence, increased erythema of the wound with or without purulence, and an unstable sternum. Infants can manifest minimal symptoms initially, with only fussiness and expiratory grunting (likely related to pain associated with respiratory effort). Fever occurs on average 5 days postoperatively, and local signs occur a mean of 9 days postoperatively.[118,194] In older children, signs and symptoms can appear later; in one study, infections were diagnosed at a mean of 15 days postoperatively.[191]

Laboratory test results usually reveal moderate leukocytosis with increased neutrophils. Typically, inflammatory markers are elevated. The diagnosis of acute suppurative mediastinitis is suggested by radiographic evidence of a widened mediastinum, mediastinal emphysema, and pleural effusions. Computed tomography and magnetic resonance imaging both have been used to diagnose mediastinitis; however, differentiating mediastinitis from postoperative changes can be difficult.[203]

Ventricular Shunt Placement.

Shunt-related infection should be suspected if a child has fever and no other localizing source and has undergone shunt placement, revision, or manipulation in the previous 3 months.[199] Children with a previous shunt infection are at increased risk.[183] Peripheral blood leukocytosis occurs frequently.[199] A sample of CSF obtained from the shunt bulb typically yields a positive culture result; positive and negative predictive values of other CSF laboratory test results are confounded by residual postoperative inflammation or by organisms causing only low-grade inflammation.

Spinal Fusion.

Infection after spinal fusion should be suspected in a child who has warmth, swelling, or excessive tenderness over the surgical incision within 3 months of the operation. Constitutional signs and symptoms of infection can be present and include fever, leukocytosis, and elevated inflammatory markers. Postoperative drains are risk factors.[204] Approximately two thirds of SSIs after spinal fusion operations occur within 30 days postoperatively, with an additional 20% of infections becoming apparent 1 to 6 months postoperatively. Approximately 10% of pediatric spinal surgical SSIs have delayed onset (>6 months) postoperatively.[167]

Management and Outcome

Antimicrobial therapy is only one aspect of management of SSIs; source control and nutritional support also are important. In patients with pyogenic abscesses, clostridial myonecrosis, streptococcal gangrene, or other infections with extensive tissue necrosis, surgical drainage or debridement is the primary treatment, and antimicrobial therapy is adjunctive. Empiric antimicrobial therapy for SSIs is based on the location of the initial surgical procedure, the suspected pathogen or pathogens, and local antibiogram. Holding therapy until acquisition of a protected specimen is desirable when safe.

Cardiac Surgery.

Surgical drainage and debridement, often with irrigation of the surgical bed, generally are required to treat postoperative mediastinitis. In patients with severe infections, the wound must be left open, with subsequent secondary closure.[205] The use of negative-pressure wound therapy can be associated with improved outcome in children who require delayed sternal closure.[185]

Empiric antimicrobial therapy is targeted at institutional cardiac SSI pathogens and the patient's endogenous flora if known; additionally, therapy also should target *S. aureus* and coagulase-negative staphylococci. No studies have been conducted to evaluate the optimal regimen or duration of antimicrobial therapy for mediastinitis; however, a course lasting 3 to 8 weeks generally is recommended, depending on the severity of the infection and the involvement of bone.[206]

Sternal osteomyelitis can accompany severe, deep mediastinal infections. These infections most commonly follow operations involving median sternotomy. Pathogens are similar to those in mediastinitis. Treatment of sternal osteomyelitis requires debridement of infected bone and a minimum of 4 to 6 weeks of antimicrobial therapy.[207]

Ventricular Shunt Placement.

Optimal management of CSF shunt infections usually entails removal of the shunt tubing and administration of systemic antibiotic therapy.[208] For children with ongoing hydrocephalus, a temporary method of CSF drainage is needed (either placement of an external ventriculostomy drain or regular ventricular taps for fluid removal) until a new shunt can be placed. Daily CSF samples are obtained to monitor the organism burden (by Gram stain), days to sterility, and in some cases cell counts and chemical values. Ventricular administration of antibiotics sometimes is required to sterilize CSF that fails to clear after several days of appropriate systemic antibiotics; however, care must be taken to ensure that the drug selected and the dose administered are appropriate and safe for direct instillation into the ventricular system.[209] Typically, several days of treatment are given after proven sterility of CSF before reinsertion of a new shunt. Antibiotic therapy is discontinued within 48 hours after placement of a new shunt system. The occurrence of infection but not the duration of initial treatment appears to affect the risk of reinfection.[183]

Spinal Fusion.

Therapy for superficial infections after spinal fusion includes systemic antibiotic therapy and enhanced wound care, which, depending on the extent of infection, can include debridement, irrigation, and packing. The management of deep SSI is challenging. Decisions about retention of grafts and prosthetic material must be considered when determining whether a wound should be closed or allowed to close by secondary intention and whether a negative-pressure dressing system should be used.[210] Selection of the appropriate agent and duration of antibiotic therapy are challenging when wound culture results are sterile or difficult to interpret.

Prevention

Key measures to prevent postoperative SSIs were introduced into surgical practice in the last century and are reviewed comprehensively.[211–213] These practices include preoperative measures such as removal of hair and application of antiseptic agents to the patient's skin, performance of surgical procedures in a properly designed and ventilated operating room, and appropriate hand antisepsis by surgical staff. Despite only limited high-quality, pediatric-specific evidence, national experts have convened working groups to develop “best practice guidelines” through consensus.

The American College of Surgeons[214] recommended perioperative antimicrobial prophylaxis when (1) prosthetic material is implanted, (2) the rate of infection is relatively high (e.g., clean-contaminated or contaminated procedures), and (3) the consequences of a postoperative infection are severe. The appropriate selection and timing of administration of perioperative antimicrobial prophylaxis have been shown repeatedly to reduce the risk of SSIs[176,215] (see Chapter 7). In a study of children undergoing general, cardiac, and spinal surgical procedures, the risk of SSI was 70% greater for patients who did not receive appropriate perioperative antimicrobial prophylaxis.[184] Although difficulties exist in establishing evidence-based recommendations for antimicrobial prophylaxis in pediatrics, the Committee on Infectious Diseases of the American Academy of Pediatrics provided recommendations based on expert consensus.[216] In addition, the guideline of the American Society of Health Systems Pharmacists provides detailed, procedure-specific recommendations on the selection and dosing of perioperative antibiotics; although these recommendations were developed for adult patients, many experts believe that they can be applied reasonably to children in most situtations.[217] General principles reiterated in guidelines include the importance of timing of the initial dose (within 60 minutes of incision), weight-based dosing for children and obese patients, and redosing for prolonged procedures and after excess blood loss.

Selection of prophylactic agents should depend on the procedure, the potentially associated pathogens, local antimicrobial susceptibility patterns, and the patient's age and hepatic and renal function. For most operative procedures that do not involve the gastrointestinal tract, cefazolin is the most commonly recommended agent because of its spectrum of activity that includes many relevant gram-positive pathogens, its serum half-life, and the low incidence of side effects. The regional prevalence of MRSA colonization among healthy children can require alteration of prophylactic strategies. Use of adjunctive agents (e.g., parenteral or topical vancomycin) for high-risk procedures (e.g., cardiac or spinal repair with placement of prosthetic material) in patients known to be colonized with MRSA is debated.[218] A meta-analysis of randomized clinical trials comparing vancomycin with a β-lactam agent for perioperative prophylaxis of SSIs in adult cardiac, vascular, or orthopedic procedures reported no difference in rates of SSI; however, investigators noted a vancomycin-associated reduced rate of infection with *Enterococcus* spp. and MRSA.[219] Large pediatric trials will be required to provide evidence-based practices for pediatric surgical patients.

Many centers develop practices based on local expertise, consensus, and available published reports. Because no benefit derives from prolonged postoperative antibiotic prophylaxis,[220] which increases the risk of wound infections caused by resistant bacteria,[164] perioperative antibiotic prophylaxis should be discontinued within 24 hours of completion of the surgical procedure.

Additional SSI prevention practices are emerging, but because high-quality evidence of efficacy in children often is limited, many of these practices have not been adopted fully by pediatric facilities. For example, the role of preoperative antiseptic bathing remains uncertain. Although it is being adopted with increasing frequency in adult and pediatric institutions, a meta-analysis performed in 2015 was unable to demonstrate that preoperative bathing with chlorhexidine gluconate was associated with lower SSI rates.[221] In contrast, multiple studies demonstrated that selective decolonization of adults known to harbor *S. aureus* reduces the risk of wound infection after high-risk orthopedic[222] and cardiac[223] operations, although substantial variation exists in the screening and decolonizing practices across US hospitals.[224] Because of the cost and complexity of identifying and decolonizing patients preoperatively, this practice is recommended only when rates of SSI remain high after full implementation of all other prevention measures.[212] Successful reductions in pediatric SSI are associated with participation in multicenter learning collaboratives.[225]

Cardiac Surgery.

Although in placebo-controlled trials antimicrobial prophylaxis was not shown to decrease the risk of pediatric mediastinitis, prophylaxis typically is used because mediastinitis can be catastrophic. The study demonstrating an increased risk of SSI among children undergoing cardiac surgical procedures who did not receive appropriate perioperative antimicrobial prophylaxis is noteworthy.[215] A review of 43 academic centers performing pediatric cardiothoracic operations showed that prophylactic antimicrobial agents frequently were continued while certain devices remained in place, such as thoracostomy or mediastinal tubes, transthoracic vascular catheters, central venous catheters, or temporary pacing wires.[226] Lack of benefit from prolonged postoperative antibiotic prophylaxis[220] and an increased risk of wound infections with resistant bacteria indicate that this practice should be abandoned.

Other preventive practices used in centers with lower rates of mediastinitis include: (1) strict adherence to aseptic technique; (2) attention to hemostasis and precise sternal closure; and (3) interventions targeted to identified risk factors.[220,227,228]

Ventricular Shunt Placement.

Prevention of SSIs after ventricular shunt placement requires adherence to the evidence-based practices described earlier. A report from the Hydrocephalus Clinical Research Network demonstrated a 36% relative reduction in the rate of infection across a 4-hospital network after adoption of a standardized protocol that included the intravenous administration of cefazolin 30 mg/kg (vancomycin 15 mg/kg for patients with substantial allergy) before incision, no use of razors for hair removal, and administration of vancomycin and gentamicin into the shunt reservoir before skin closure.[183] The role of antibiotic-impregnated shunt tubing remains unclear. Although many small retrospective studies did not find a difference in SSI rate among children who did and did not receive an antibiotic-impregnated shunt,[229–231] a large study conducted in the United Kingdom found that the use of an antibiotic-coated shunt was associated with a 40% reduction in the risk of SSI.[232] A meta-analysis concluded a lower SSI risk with "unclear degree of clinical certainty."[233] Additional study is needed.

Spinal Fusion.

Unfortunately, high-quality evidence to guide recommendations to prevent SSI after spinal fusion in children is limited. A group of orthopedic surgeons and infectious diseases specialists used the Delphi process to identify consensus practices.[218] A total of 14 prevention strategies were recommended for use in all spinal fusion procedures other than initial fusion for idiopathic scoliosis in patients without comorbid conditions. Key elements of this best practice guideline include (1) preoperative nutritional assessment, (2) a chlorhexidine gluconate bath the night before the operation, (3) perioperative antimicrobial prophylaxis that targets both skin and enteric organisms, (4) monitoring of adherence to perioperative antimicrobial regimens, and (5) limited movement into and out of the operating room during the procedure.[218] Participating centers are currently gathering data to assess the impact of these practices on SSIs.

Clinical Syndromes of Device-Associated Infections

Julia S. Sammons, Jeffrey S. Gerber

The use of medical devices has increased dramatically over recent decades.[1] In children, the most common device-associated infections involve intravascular catheters; cardiac devices, such as prosthetic valves, patches, vascular grafts, pacemakers, and ventricular assist devices; cerebrospinal fluid shunts; peritoneal dialysis catheters; orthopedic implants; and urinary catheters. Such infections contribute to the substantial burden of emergency department visits, hospitalizations, and nosocomial illnesses in children.[2,3] This chapter addresses device-associated infections in children beyond the neonatal period. For device-associated infections in the neonate, see Chapter 94.

Certain general principles apply to infections involving medical devices. Factors that influence the risk for developing a device-associated infection include the properties of the device, of potential pathogens, and of the host (Box 100.1).[4] In addition, colonization and subsequent infection associated with medical devices are facilitated by biofilm formation—a complex matrix of colonizing organisms and extracellular proteins.[5,6] Immediately after implantation, biofilms begin to form with the deposition of host proteins on the device surface. Microorganisms adhere, multiply, and contribute additional extracellular proteins to this coating. Properties inherent to biofilms can inhibit host defenses[7,8] and sequester organisms away from antimicrobial agents.[9–11]

Box 100.1

Determinants of Medical Device–Associated Infections

Properties of the Device

Material: inert, plastic, rubber

Design: hollow, solid

Location: implanted, percutaneous, vascular/nonvascular site

Properties of Potential Pathogens

Source: endogenous, environment, contaminated disinfectant/device/solution

Susceptibility: in vitro and in biofilm

Properties of the Host

Host defenses: skin, mucous membranes, immune system

Medication: anti-inflammatory agents, immunosuppressive agents

Altered flora due to diet, medications (antacids, antimicrobial agents)

The microbiology of device-associated infections varies by device (Box 100.2). Organisms found as part of the normal skin flora are the most common etiologic agents in foreign body infections in infants and children.[8,12] Certain species are particularly well suited to colonizing devices. *Staphylococcus aureus* adheres specifically to fibrinogen, a component of biofilms.[13,14] Coagulase-negative staphylococci (CoNS), *Pseudomonas aeruginosa,* and *Corynebacterium* spp. produce proteinaceous slime, capsular polysaccharides, and adhesins that enhance adherence and protect the organism from host defenses and the effects of antimicrobial agents.[12,15–17]

Staphylococcus aureus

Other skin flora

Common

Gram-negative enteric bacilli

Environmental organisms

Candida spp., especially *C. albicans* and *C. glabrata*

Occasional

Other fungi

Nontuberculous mycobacteria

Common clinical findings in foreign body infection include malfunction of the device (e.g., occlusion of catheters and shunts or loosening of prosthetic joints),[18,19] pain at the site of the device or insertion site, and failure of wound healing after implantation. Fever, leukocytosis, and other systemic signs can be absent; thus, a high index of suspicion is required for timely diagnosis. Cultures are essential to both establish the diagnosis and guide definitive therapy. Antimicrobial therapy alone sometimes is curative, but frequently the foreign body must be removed. The risk for device-associated infections can be reduced by consistent application of several principles and evidence-based practices, referred to as "bundles."[20] Devices should only be used in circumstances in which they are essential and, when feasible, removed as soon as possible; strict aseptic technique must be observed during insertion or manipulation of a device; and the frequency of device access or manipulation should be limited to reduce the likelihood of contamination. Although the use of antimicrobial prophylaxis at the time of insertion is commonplace, the efficacy of such measures for many devices has not been established.[21–23] Recent advances in materials used for catheters and prosthetic devices have resulted in decreased rates of infection. The use of central venous catheters (CVCs) impregnated with either minocycline and rifampin or chlorhexidine and silver sulfadiazine has been shown to be effective in reducing the incidence of both catheter colonization and central line−associated bloodstream infection (CLABSI) in adult patients[24–26]; however, few efficacy studies of these devices have been performed in children.[27–31]

Intravascular Catheter-Related Infections

Epidemiology and Pathogenesis

With focused prevention efforts, rates of CLABSI in the United States have decreased dramatically. The Centers for Disease Control and Prevention (CDC) National Healthcare Safety Network (NHSN) reporting system noted a 46% decline in CLABSI between 2008 and 2013.[32] Still, device-associated infections comprise approximately 25% of all healthcare-associated infection (HAI) reported to NHSN,[33] and CLABSIs represent the most common device-associated infection experienced by hospitalized children.[32] Critically ill children who develop CLABSI have longer duration of intensive care unit (ICU) and hospital stay, and the crude attributable mortality has been estimated to be 19%.[34] In addition, using a propensity score matched case-control study, the attributable cost and length of stay between matched CLABSI cases and non-CLABSI controls was found to be $55,646 (2011 dollars) and 19 days, respectively.[35]

The terminology describing catheter-related infections can be confusing. Catheter-related bloodstream infection (CRBSI) identifies the catheter as the source of infection. CLABSI, however, is a term used by NHSN to facilitate surveillance (and, therefore, has been widely adopted as a surrogate for CRBSI in the literature describing its epidemiology) and may overestimate the true incidence of CRBSI. Also, several different types of CVCs are used in children. A CVC generally is classified by its intended duration of use (short term vs. long term); its site and mode of insertion (peripheral, femoral, subclavian; tunneled vs. nontunneled); or other specific characteristics (antibiotic-coated, multilumen). Lastly, multiple types of catheter-related infections can be identified. Infection can occur at the exit site, in the subcutaneous tunnel or pocket, or in the bloodstream.[36] Pathogens can be introduced during insertion, manipulation, calibration, and flushing of monitoring devices (all modes of direct contamination influenced by hand hygiene practices), or through contaminated parenteral fluids, flush solutions, or skin antiseptics. Translocation of organisms from colonizing sites with resultant transient bacteremia also can lead to CLABSI. (Box 100.3).[37–41]

EXTENSION OF LOCAL INFECTION

Gram-positive organisms, including CoNS, *S. aureus,* and enterococci, are most commonly isolated in intravascular catheter-associated infections.[34,42–44] In fact, although incidence density rates of CLABSI have decreased overall in recent years, the incidence density rate of *S. aureus* CLABSIs among pediatric ICUs in the US has remained the same.[45] Identification of gram-negative bacilli, including *Enterobacter* spp., *P. aeruginosa, Klebsiella pneumoniae,* and *Escherichia coli,* has increased to approximately one third of reported infections (Box 100.4).[44] *Candida* spp. are increasingly prevalent and now are the fourth most common cause of nosocomial bloodstream infection (BSI) in the US.[44,46–48] Among 29 hospitals participating in the Children's Hospital Association Quality Transformation Network, the majority of CLABSIs in pediatric ICUs were caused by a single organism, most commonly gram-positive cocci.[49] Of *S. aureus* isolates, methicillin-resistant *S. aureus* (MRSA) represented nearly 50%. Gram-negative bacilli were identified in one third of cases and *Candida* spp. in 15%. Other relatively common organisms include *Corynebacterium, Propionibacterium,* and *Bacillus* spp., *Serratia marcescens, Acinetobacter* spp., *Citrobacter* spp., and nontuberculous mycobacteria.[36] The frequency and distribution of organisms may be influenced by the child's exposure to (or level of illness associated with) the ICU[50] particular medications, such as intravenous (IV) prostanoid agents[51] or underlying cancer or chemotherapy.[52,53]

Catheter-Related Factors

Risk for infection varies by catheter type. Rates are higher for CVCs than for peripheral venous or arterial catheters.[36] Although some studies showed similar infection risks for tunneled and nontunneled catheters,[54,55] later randomized studies showed that tunneling of femoral catheters[56] and internal jugular catheters[57] is associated with lower infection risk (Box 100.5). Peripherally inserted central catheters (PICCs) now are used more commonly because of their perceived lower risk for infection; however, two outpatient studies demonstrated a 10% PICC infection rate,[58,59] and analyses of critically ill patients have revealed that the risk for catheter infection is similar among patients with a PICC and those with a centrally inserted percutaneous catheter.[60] A correlation between increasing number of lumens and incidence of infection has been noted in some studies, but not others.[61,62] In addition, the presence of multiple venous catheters was found to be an independent risk factor associated with nosocomial BSIs.[34] The site of placement determines the types and burden of organisms in proximity to the catheter entry site because organisms present at the site of catheter insertion can move from the entry site along the dermal tunnel to the catheter tip within hours.[63] Quantitative cultures of potential catheter sites in adults and neonates show that the upper extremity and chest wall have the lowest burden of bacteria, whereas the groin and jugular areas are more heavily colonized.[64] In adults, catheters placed in the groin are associated with a greater risk for infection than those placed in the neck[65];

however, this does not appear to be consistently supported in pediatric studies,[49,66–69] and recent guidelines do not support preferential placement in children.[41,43]

Immune competence

The duration of catheter placement is directly related to the risk for infection, a concept that has been substantiated in multiple pediatric studies.[50,70–74] Biofilm formation, which increases with dwell time, clearly increases the opportunity for catheter colonization. In addition, each manipulation of a catheter, stopcock, or needleless device provides an opportunity for the introduction of organisms.[36,75,76] Outbreaks of bacteremia have resulted from contamination of pressure transducers.[65,77–80] Replacing the catheter over a guidewire does not decrease the incidence of infection, and may even increase it.[81] Finally, the effect of transparent versus gauze dressing use on infection risk remains an unresolved issue.[82] A recent meta-analysis found an association between CLABSI and transparent dressing use; however, the source studies for the meta-analysis were of low quality.[82–84]

Certain infusates are more likely than others to be associated with BSI. Use of parenteral nutrition fluids increases the risk for CLABSI in multiple pediatric studies.[50,71,85,86] In addition, receipt of blood transfusion has been identified as an independent risk factor for CLABSI in pediatric ICU patients.[87,88] Intrinsically or extrinsically contaminated infusates also can cause CLABSI. Although intrinsic contamination of intravenous fluids is rarely reported in the US, episodes of extrinsic contamination of intravenous fluids and medications continue to occur.

Host Factors

Host factors influence the risk of CLABSI. Skin flora varies according to a person's hygiene and medications. Topical antimicrobial agents may alter the nature and density of local flora, and chlorhexidine gluconate (CHG) is now the preferred agent for preinsertion decontamination and daily maintenance (see "Prevention" section later). Systemic antimicrobial agents alter stool and skin flora and increase the risk for infection by *Candida* spp.[72,89] Factors that lead to a break in the integrity of skin or mucous membranes can increase the risk for catheter infections. Thus patients with immature skin (premature infants), impaired integrity of the gut epithelium (patients with short-gut syndrome),[90,91] or burn patients may be at risk for bacteremia and subsequent colonization of an indwelling catheter, although the true contribution of these putative mechanisms (as opposed to confounding risks such as illness severity and increased need for intravascular access) remains unclear. Similarly, patients with a distant site of infection (such as an abscess) or who develop a spontaneous bacteremia are also at risk for developing a secondary CRBSI.

Children undergoing cancer chemotherapy are at risk for infection because of neutropenia; infection rates in these patients are increased 2- to 4-fold by the use of indwelling CVCs.[92] In addition, mucositis may raise the risk for bacterial gastrointestinal wall translocation and bacteremia and may account for differences in the microbiology of BSIs that occur in neutropenic, compared with nonneutropenic, patients. In a prospective study of more than 24,000 episodes of nosocomial BSIs, neutropenic patients were at greater risk for infection due to *Candida* spp., enterococci, and viridans group streptococci.[93] It remains unclear, however, whether the increased infection rate and variable microbiology are attributable to mucositis or to the associated illness severity, immune suppression, and care environment of such patients. In light of these issues, the CDC recently incorporated a new category for CLABSI surveillance known as *mucosal barrier injury–laboratory confirmed bloodstream infection* (MBI-LCBI); these infections include primary BSI due to select organisms in patients with neutropenia or in patients with allogeneic hematopoietic stem cell transplantation with gastrointestinal graft-versus-host disease or diarrhea.[94,95]

Patients with human immunodeficiency virus (HIV) infection are at greater risk for a variety of infections; use of CVCs for nutritional support and for medications increases the risk for bacteremia in HIV-infected and other patients.[96,97] Patients with uremia are at higher risk for CLABSI, particularly those with hemodialysis catheters.[98–100] In patients undergoing hemodialysis, the type of bloodstream access used influences the risk for infection; the risk is lowest with native arteriovenous fistulas, intermediate with artificial arteriovenous grafts, and highest with CVCs.[101,102]

Clinical factors related to the severity of illness also have been found to influence the risk for infection. In a cohort of critically ill pediatric patients, the need for transport out of the care unit and for a procedure performed within an ICU were both independently associated with a 3- to 4-fold increase in the risk for developing a nosocomial BSI.[34] Need for ICU exposure, ICU placement of the central line, mechanical ventilation, medical cardiac disease, malignancy, genetic syndrome, metabolic disease, presence of a gastrostomy tube, and history of prior CVC also have been associated with CLABSI in children.[50,70,71,85,87,88]

Clinical Manifestations and Laboratory Diagnosis

Fever usually is present in patients with catheter-related infections. Patients with localized infection of the exit site, pocket, or tunnel frequently have infection in the absence of fever. When a catheter-related infection is suspected, the exit site should be examined for the presence of local suppuration or cellulitis; however, normal appearance of the exit site does not exclude a local or systemic infection involving the catheter. Any catheter malfunction (including decrease in flow or unidirectional flow) should prompt an evaluation for infection. Findings suggestive of disseminated infection include the presence of emboli in the retina, skin, bone, and viscera (lungs, kidneys, liver, and spleen) and organ dysfunction due to immune complex deposition (e.g., nephritis).

Infections attributable to a CVC include exit, tunnel, and pocket infections as well as BSI (Table 100.1).[103] A CRBSI is defined as bacteremia or fungemia in a patient with a centrally placed intravascular catheter in which the catheter is the presumed source of infection. Establishing that the catheter is the source of infection is not always straightforward. For example, a BSI in a patient with an indwelling catheter can originate from an undocumented source of infection (e.g., a postoperative wound infection or a urinary tract infection [UTI]) rather than from the catheter. In adult patients, only 15% to 20% of CVCs removed in the context of a BSI are implicated ultimately as the primary source of infection.

TABLE 100.1

Types of Catheter-Related Infections

Infection	Clinical Diagnosis
Exit site infection	Erythema or induration within 2 cm of catheter exit site
Tunnel infection	Tenderness, erythema, or induration along the subcutaneous tract of a tunneled catheter and more than 2 cm from catheter exit site
Pocket infection	Purulent fluid in the subcutaneous pocket of a totally implanted venous access device. May be accompanied by overlying tenderness, erythema, induration, visible drainage, and skin necrosis

Catheter-associated bloodstream infection	Positive simultaneous blood cultures from the central venous catheter and peripheral vein yielding the same organism in the presence of at least one of the following:
	▪ Simultaneous quantitative blood cultures in which the number of CFUs/mL isolated from blood drawn through the central catheter is ≥5-fold the number isolated from blood drawn peripherally
	▪ Positive semiquantitative (≥15 CFUs/catheter segment) or quantitative (≥100 CFUs/catheter segment) catheter tip cultures
	▪ Simultaneous blood cultures of equal volume in which the central blood culture has growth in an automated system ≥2 hours earlier than the peripheral blood culture

CFU, colony-forming unit.

Several methods have been used to identify the catheter as the source of infection, although no microbiologic gold standard for diagnosis of catheter-related BSIs exists.[104] Proposed methods include quantitative cultures of blood obtained through the catheter and a peripheral vein simultaneously; quantitative and semiquantitative cultures of a catheter segment; and differential time to blood culture positivity[105] (see Table 100.1). Until recently, the most commonly accepted methods of diagnosing a CRBSI have involved either quantitative or semiquantitative cultures of the catheter tip. This strategy relies on the prompt removal of the catheter and is thus not appropriate in many clinical settings. A positive catheter culture result is defined as growth of at least 15 colony-forming units (CFU) on an agar surface over which the catheter tip was rolled.[106] An alternative method involves sonicating the catheter tip in fluid to dislodge the intraluminal biofilm; this method is associated with a higher rate of positive cultures than the roll technique.[107] A catheter tip culture that yields ≥15 CFU is a valid indication of catheter colonization, which in turn is associated with a higher risk for BSI. However, a relatively small number of patients with colonized catheters have CRBSI.[108] In fact, electron microscopy of catheter tips reveals universal colonization with bacteria.[107,109] Thus the positive predictive value (PPV) of a positive catheter tip culture result is low, ranging from 5% to 30% in most studies, and this method has not been evaluated for antimicrobial agent- or antiseptic-impregnated catheters.

Differential time to positivity of paired blood cultures is the simplest of the three methods and does not require specialized laboratory culture methods (other than a continuous-monitoring blood culture system) or catheter removal, but requires that peripheral and central cultures are drawn simultaneously and are of equal volume. If the same organism is isolated from both blood cultures and the time to positivity of the catheter-obtained specimen is >2 hours shorter than that of the peripherally obtained culture, catheter colonization and CRBSI are likely.[105,110] Compared with quantitative and semiquantitative methods, differential time to positivity of >2 hours had a sensitivity of 93% and a specificity of 75% for catheters in place for >30 days and a sensitivity of 81% and a specificity of 92% for catheters in place for <30 days.[111] Several smaller studies have demonstrated similar results.[112–114] In an analysis of semiquantitative cultures obtained from different lumens of multilumen catheters in pediatric oncology patients with double-lumen catheters in place and no peripheral blood cultures available, PPV of more than fivefold difference in CFU/mL of isolates from samples from the two lumens was 92% predictive of a CRBSI.[115]

Few studies have evaluated the optimal timing of blood cultures, although timing should be guided by patient acuity. Compared with obtaining multiple specimens at the same time, obtaining multiple samples over a 24-hour period appears to increase the ability to detect intermittent bacteremia.[114,116] In patients already receiving antibiotics, samples obtained close to the time that antibiotic concentrations have reached trough levels (i.e., just before next dose) theoretically could improve recovery of organisms in blood cultures[117]; however, this issue has not been studied and may not be practical clinically.

The volume of blood that is obtained is the most important factor in successfully recovering bacteria and fungi.[104,118] Studies have demonstrated that the likelihood of growth is lower and the time to detection is delayed when small volumes (<0.5 mL) of blood are used to inoculate blood culture bottles[108]; however, advancements in blood culture detection system technology continue to improve in efficiency. Although multiple cultures enhance the recovery of pathogens, the volume of blood cultured may be more important than the total number of blood cultures obtained. One study found that the pathogen recovery rate at 24 hours was 72% for a large-volume (6 mL) single culture compared with a 47% combined yield of two smaller (2 mL) samples inoculated into separate culture bottles.[119] Similar results were found in studies of adult patients in which standard "adult-volume" cultures (mean, 8.7 mL) had a higher detection rate (92%) than "low-volume" cultures (mean, 2.7 mL), in which the detection rate was only 69%.[120] Investigators estimated that the yield of adult blood cultures increased approximately 3% per mL of blood cultured.

Other technical issues can affect the sensitivity of blood cultures. Diluting the blood into the blood culture broth enhances recovery of pathogens, perhaps by diluting antimicrobial agents (if applicable) and blood components such as phagocytes, antibodies, and complement factors that are known to have bactericidal activity.[121] The ideal blood-to-broth ratio depends on the blood culture system used, but a ratio between 1 : 5 and 1 : 10 generally is considered ideal[122]; it is essential to identify the optimal blood volume suitable for the culture system in one's clinical microbiology laboratory. For recovery of certain bacteria, fungi, and mycobacteria, special handling of blood cultures is required. For example, filamentous fungi require solid media for growth, *Malassezia furfur* requires lipid supplementation, and certain gram-negative species and some mycobacteria need prolonged incubation (see Chapter 286). Failure of culture to identify a pathogen in the patient with continued clinical evidence of infection should prompt consideration of less common, more fastidious organisms and discussion with microbiology laboratory personnel about additional collection, culture and detection techniques.

Distinguishing between cultures that represent "contamination" and those that represent "true" BSI can be challenging, especially when a skin organism (e.g., CoNS, *Bacillus* spp., micrococci) is isolated. Obtaining multiple cultures can clarify most situations. A study using a mathematical model of blood cultures positive for CoNS in patients with a CVC found that the PPV of a single positive culture (if only one culture was obtained) was 55%; however, if only 1 of 2 cultures obtained was positive, the PPV was 20%, and if only 1 of 3 cultures was positive, the PPV was only 5%. Investigators developed a similar model for blood culture positivity depending on sampling site. If 2 of 2 cultures were positive, the PPV was 98% if both samples were obtained from a peripheral vein, 96% if 1 sample was obtained through a catheter and the other was obtained through the vein, and only 50% if both samples were obtained through a catheter.[123] Furthermore, the distinction between pathogen and contaminant is influenced by age and underlying conditions. Although CoNS often is considered a true pathogen in neonates, this issue remains controversial.[124] Because the isolation of CoNS from a blood culture often results in a clinical intervention and administration of vancomycin, it is particularly important to obtain multiple blood cultures. Overuse of vancomycin has implications for adverse events, and the continued increase of vancomycin resistance among gram-positive organisms.[125–127]

Repeatedly positive blood culture results despite appropriate antimicrobial therapy suggests the presence of an intravascular focus of infection such as the catheter itself, complicating suppurative thrombophlebitis or endocarditis (especially if the catheter has been removed).[128,129] Among patients with intravascular catheters, the risk for endocarditis is highest with Swan-Ganz catheters and lowest with peripheral catheters. In an autopsy series, 53% of patients who had undergone pulmonary artery catheterization had right-sided endocardial lesions; 7% had infective endocarditis.[130] Centrally placed catheters often traverse and damage the tricuspid valve, increasing the risk for right-sided endocarditis. Thrombi within the heart can become infected or can obstruct outflow.

Ultrasonography is useful in detecting thrombosis of vessels or formation of vegetations. The value of a negative transcutaneous ultrasonography result is debated; in adults, the use of transesophageal echocardiography increases the likelihood of detecting intracardiac vegetations.[131] Gadolinium-enhanced magnetic resonance venography can be useful in detecting central venous thromboses.[132]

Management and Outcome

Exit site infections can be treated by removal of the catheter and local care. If the catheter remains in place, local topical therapy can be successful in controlling this type of infection; however, systemic antimicrobial therapy and catheter removal usually are required if an exit site infection extends to involve the soft tissues that surround the catheter (i.e., the subcutaneous tunnel or pocket) or is associated with a CLABSI. Limited data guide the management of

CLABSI in children. Even in adults, there are insufficient randomized or controlled studies to address optimal management of CLABSI.[105] To help address this uncertainly, the Infectious Diseases Society of America has published guidelines for the diagnosis and management of CLABSI. Although focused on adult patients, this guideline contains recommendations for the management of children with CLABSI and is endorsed by the Pediatric Infectious Diseases Society.[105]

Empiric therapy in children with suspected CLABSI should include an antimicrobial agent with activity against gram-positive bacteria, such as nafcillin, oxacillin, or vancomycin, and an agent effective against gram-negative bacteria, including *Pseudomonas* spp., such as ceftazidime or cefipime. The empiric use of both an antipseudomonal β-lactam and an aminoglycoside may be appropriate in severely ill patients or when infection with a resistant gram-negative organism is suspected. In institutions in which MRSA is prevalent, the use of vancomycin is appropriate. Aztreonam or fluoroquinolones can be used when β-lactam allergy is present and broad-spectrum gram-negative coverage is required.

Limited data guide clinical decisions regarding the need for catheter removal (Table 100.2). In adults with CLABSI, it is recommended that most nontunneled CVCs be removed.[105] In children, removal of a catheter may not always be feasible because of the potential for complications associated with reinsertion and limited vascular access sites. Children treated without catheter removal should be monitored closely and additional blood cultures drawn; the catheter should be removed with clinical deterioration or persistent or recurrent CLABSI. In patients with CLABSI associated with a tunneled catheter or implantable device such as a port catheter, the decision to remove the catheter is more complicated; however, good evidence favors the removal of the CVC in patients with evidence of a tunnel infection or infection in the subcutaneous pocket of an implanted device.[105] When culture data are available, treatment decisions can be tailored to the specific organism isolated. Several studies have reported successful treatment of CLABSI without catheter removal, depending on the pathogen identified.[133–136]

TABLE 100.2

Management of the Catheter in Patients With a Central Venous Catheter−Related Infection

Type of Infection	Catheter Management
Exit site infection	Remove CVC if:
	▪ No longer required
	▪ Alternate site exists
	▪ Patient critically ill (e.g., hypotension)
	▪ Infection due to *Pseudomonas aeruginosa* or fungi
Tunnel infection	Remove CVC
Pocket infection	Remove CVC
Catheter-related bloodstream infection	Remove CVC if: ▪ No longer required
	▪ Infection caused by *Staphylococcus aureus, Candida* spp., or mycobacteria
	▪ Patient critically ill
	▪ Failure to clear bacteremia in 48–72 hours
	▪ Persistent symptoms of bloodstream infection beyond 48–72 hours
	▪ Noninfectious valvular heart disease (increased risk for endocarditis)
	▪ Endocarditis
	▪ Metastatic infection
	▪ Septic thrombophlebitis

CVC, central venous catheter.

The aforementioned management guideline also includes the use of antimicrobial lock therapy in management of CLABSI when catheter salvage is the goal.[41] The concept underpinning lock therapy is that bacteria embedded in biofilms on intraluminal surfaces of catheters may be killed more effectively by antibiotic concentrations 100 to 1000 times higher than standard concentrations of intravenous antibiotics. Lock solutions typically are mixed with heparin in sufficient volumes to fill the lumen, allowed to dwell, then removed. This approach is currently recommended in conjunction with systemic therapy for select organisms.[41]

Few data exist regarding the duration of antibiotic therapy for CLABSI. The duration of therapy depends in part on the pathogen; whether the catheter is removed; and whether infection is complicated by septic thrombosis, endocarditis, osteomyelitis, or other metastatic foci of bacteria. For complicated infections, the duration of therapy is based on the length of therapy needed to treat the suppurative complication. There are no data to determine the optimal duration of intravenous versus oral antibiotics for the treatment of CLABSI when the catheter is removed. Certain antibiotics with excellent oral bioavailability may be considered an alternative to parenteral therapy after the catheter has been removed (or lock therapy begun), the BSI has cleared, and the patient has shown clinical improvement. Some pathogen-specific recommendations are provided below.

Coagulase-Negative Staphylococci (Other Than *S. lugdunensis*)

A relatively low-virulence organism, CoNS infection usually presents with fever alone or catheter malfunction, with or without inflammation at the catheter exit site. CoNS CLABSI can resolve with catheter removal alone, although guidelines recommend a short course of antibiotic therapy (3–5 days) even after removal of the catheter.[105] If the catheter is retained, the recommended duration of treatment is 10 to 14 days after a negative culture from blood drawn through the CVC has been obtained. In neonates with CoNS BSI, treatment without removal of the catheter can be attempted; however, if a neonate has 3 positive blood cultures despite appropriate antimicrobial therapy, the catheter should be removed because of the increased risk for end-organ damage[137] (see Chapter 94). The relapse rate in adults with CoNS CLABSI is 20% if the catheter is not removed, compared with 3% if the catheter is removed.[138]

Staphylococcus aureus

Serious complications, including endocarditis and other deep tissue infections, have been reported in association with *S. aureus* CLABSI.[40,129] Adults with *S. aureus* BSI who have a medical device are at substantial risk for endocarditis; echocardiography is performed routinely as part of management.[139,140] In contrast, the frequency of infective endocarditis is low in children with structurally normal hearts who have *S. aureus* BSI; therefore, echocardiography is not recommended routinely.[141] In a prospective study of 51 children with *S. aureus* BSI, definite or possible endocarditis was diagnosed in 52% of patients with congenital heart disease but in only 3% of children with structurally normal hearts.[141] Echocardiography should be considered in children with (1) prolonged BSI before treatment, (2) persistent BSI while receiving appropriate antimicrobial therapy, (3) a new murmur identified on physical examination, or (4) congenital heart disease. Neonates may be more vulnerable than older infants to complications of *S. aureus* BSI.[137] Some experts recommend catheter removal for neonates with a single positive blood culture when *S. aureus* or a gram-negative bacillus is the isolate because this significantly improves outcome. Two weeks of appropriate antimicrobial therapy, chosen based on susceptibility test results, is recommended for uncomplicated *S. aureus* CLABSI.[90] Longer duration of therapy (4–6 weeks) may be necessary for patients with prolonged BSI (>3 days), persistent fever, or complicated infection.[142]

Gram-Negative Bacilli

Few data address the appropriate duration of therapy and the need for catheter removal in patients with CLABSI caused by gram-negative bacilli. In general, for uncomplicated infections, antimicrobial therapy should be administered for 10 to 14 days after documented blood culture negativity.[105] Although children with CLABSI caused by gram-negative bacilli have been successfully treated without catheter removal, catheter removal has been shown to be beneficial in the treatment of infections with specific gram-negative bacilli such as *Pseudomonas* spp., *Burkholderia cepacia, Acinetobacter baumannii,* and *Stenotrophomonas* spp.[40,103] In a study of adults with CLABSI caused by gram-negative bacilli, catheter removal was associated with a reduced rate of relapse.[143]

Candida Species

Treatment of candidemia without removal of the catheter has been associated with poor outcomes in children and adults[144–146]; however, these studies have not accounted for confounding effects of the severity of illness.[147] Failure to remove the catheter promptly is associated with prolonged candidemia, which in turn has been associated with higher rates of disseminated infection. However, a recent retrospective study among adults with catheter-associated candidemia found no difference in outcomes between early versus late catheter removal, but the study did not address long-term outcomes such as recurrence.[148] In a study of 153 children with candidemia, the overall rate of disseminated candidiasis (to lung, liver, spleen, eye, brain, heart) was 17%; the crude mortality rate was 26%.[149] Guidelines recommend that catheters should be removed in patients with candidemia whenever clinically feasible.[150] Patients with candidemia should be treated with an echinocandin, amphotericin B, or fluconazole for at least 2 weeks. Azole susceptibility testing should be performed for all bloodstream isolates, and echinocandin testing is done for those from patients previously treated with an echinocandin and for non-*albicans* species.[150] Many experts would recommend performance of an ophthalmologic examination to evaluate for candidal endophthalmitis, preferably after the infection is controlled and further disseminated disease is unlikely.[150] Risk for dissemination is multifactorial, depending on the pathogen, host, and duration of candidemia.

Nontuberculous Mycobacteria

Infections due to nontuberculous mycobacteria should be managed by removal of the catheter and antimicrobial therapy. The choice of agents is individualized. The empiric combination of clarithromycin and tobramycin *(M. chelonae),* amikacin and meropenem *(M. fortuitum),*[151,152] or other drugs in combination should be considered depending on the species of pathogen and expected and then proven antimicrobial susceptibility.

Complications

Complications of CRBSI include thrombosis with or without thrombophlebitis, sepsis, septic endocarditis, and metastatic infection with seeding of bone and organs (lung, kidneys, liver, spleen, brain, skin). The prognosis for patients with CRBSI is influenced by factors related to the pathogen, host, and therapy. If the infection is recognized and appropriate antimicrobial therapy is instituted promptly, there can be a high rate of cure, and even salvage of the catheter; delayed treatment is associated with increased morbidity and mortality.[105]

CVC-related thrombosis is common. In one study of children who had CVCs for home parenteral nutrition, venography revealed blockage of central vessels in 66%.[153] In a study of femoral venous catheters, evidence of thrombosis was found in 69% of children. Positive blood culture results were obtained in 38% of patients who had thrombosis versus 3% of patients who did not. The incidence of thrombosis was lower in patients who had heparin-bonded catheters.[154] If a patient with a thrombosed vessel develops BSI, the clot can become infected and lead to thrombophlebitis and persistent BSI.[155] The optimal treatment for septic thrombophlebitis of a CVC is unclear. Phlebitis of peripheral veins is commonly delayed in onset, often becoming apparent ≥24 hours after removal of the catheter.[156,157] Suppurative thrombophlebitis sometimes resolves after catheter removal. Fluctuance at a subcutaneous venous site; persistent erythema, swelling, and tenderness; or persistent BSI despite antimicrobial therapy are clues that aspiration, surgical drainage, or resection of the vein may be necessary for cure.[158] Removal of the catheter and prompt therapy with appropriate antimicrobial agents are essential. Although urokinase has been demonstrated to be effective in restoring catheter patency in up to 75% of patients with occluded catheters,[159] the role of anticoagulation or thrombolytic agents in the face of a catheter infection is uncertain.

Overall, fatality rates for CLABSI are 10% to 25%, with rates as high as 50% in critically ill patients and neonates.[160,161] One study demonstrated that only the presence of underlying malignancy or immunodeficiency was independently associated with an increased risk for mortality due to a CLABSI.[162] Relapse of a catheter-associated infection can occur, and reinfection with a new organism is more common in catheters that have been infected previously.[142,151] Frequent recurrences should raise concerns regarding the care of the catheter, particularly in children who are outpatients. Munchausen syndrome by proxy has been implicated as a cause of recurrent central catheter septicemia.[163]

Prevention

The elimination of CLABSI in all patient care areas is the stated goal of many national organizations.[43] Although this target has not been reached in many pediatric settings, considerable progress has been made, particularly within the context of organized initiatives and with use of care bundles for both catheter insertion and maintenance[20,164–166] (see Chapter 2). Still, the success of bundled practices depends on adherence to the individual elements and is optimized in settings with a preexisting culture of patient safety.

The simplest way to reduce the risk for CLABSI is to avoid catheterization (Box 100.6). If a catheter is essential, however, a variety of practical measures can be taken to lower the risk for CLABSI.[41,167,168] Catheters that are no longer needed should be removed promptly. The presence of an idle catheter is common, accounting for 20% of catheter days in one study, and poses an unacceptable risk to the patient.[169] Performance of hand hygiene and the use of maximal barrier precautions (the wearing of sterile gloves, long-sleeved sterile gown, mask, and cap and the use of a large sterile sheet drape) before and during insertion of central catheters help reduce infection risk substantially.[170] In addition, use of checklists, as well as all-inclusive catheter carts or kits, can help to ensure that optimal insertion practices are followed.[41] These measures have been shown to be cost-effective over a wide variety of clinical conditions.[171]

Box 100.6

Prevention of Vascular Catheter-Related Infections

General

Avoid unnecessary catheter insertion

Remove unneeded catheters as soon as possible

Catheter Insertion

Apply skin site antisepsis; use chlorhexidine gluconate for central venous catheter placement

Use strict aseptic technique

Use sterile technique and maximal barrier precautions when inserting central venous or arterial catheters

Catheter Care

Minimize manipulation of catheters

Perform hand hygiene before and after palpating, inserting, replacing, or dressing any catheter

Perform catheter site care (chlorhexidine); consider use chlorhexidine biopatch

Inspect hub design; avoid preslit cover

Prepare hub before injection or aspiration through the hub

Replace end caps frequently

Catheter Selection

Select a catheter with the fewest lumens needed for management of the patient

Consider use of antiseptic- or antimicrobial-coated central catheters and silver-impregnated, collagen-cuffed catheters when infection rates remain high despite other measures (e.g., maximal barrier precautions)

For long-term (>30 days) access in children older than 4 years, consider peripherally inserted central catheters or tunneled or totally implantable devices; for children younger than 4 years, consider totally implantable devices

Stopcocks

Cover all openings

Minimize use

Monitoring Devices (Transducers, etc.)

Sterilize if being reused; avoid contamination during use

Careful skin antisepsis before insertion is an important preventive measure. Several randomized trials have demonstrated that antisepsis with 2% chlorhexidine is superior to povidone-iodine for preventing CLABSI,[172–174] and an alcoholic chlorhexidine antiseptic is now recommended for skin preparation before CVC insertion.[41] Further, numerous studies have demonstrated the benefit of daily chlorhexidine bathing in reducing CLABSI and other HAIs in adult settings[175–180] and in pediatric ICUs[181]; this practice is now recommended for all ICU patients with CVCs.[34,41] The optimal choice of antiseptic agent for children <2 months of age remains an unresolved issue, although chlorhexidine products frequently are used in neonatal populations,[182] and daily chlorhexidine bathing has been shown to reduce rates of CLABSI in a tertiary care neonatal ICU.[183] The U.S. Food and Drug Administration (FDA) recommends "use with care in premature infants or infants under 2 months of age; these products may cause irritation or chemical burns." Routine changing of percutaneously inserted lines over guidewires should not be performed to prevent infection[81,167] or to replace a catheter with suspected infection.[34] Systemic antimicrobial prophylaxis before insertion of the CVC or for catheter maintenance has not been demonstrated to reduce the risk for CRBSI and is not recommended.[34,41,168,184] Continuous infusion of vancomycin through the CVC was effective in reducing CoNS BSI in neonates in one study, but did not reduce either length of stay in the ICU or mortality.[185] Moreover, routine use of systemic vancomycin for prophylaxis carries the risk for inducing vancomycin resistance and is not recommended.[186]

Attention to daily catheter care and maintenance is essential to preventing infection. Hand hygiene should be performed before any catheter manipulation. Education and training of staff, as well as ensuring appropriate staffing levels, are paramount.[34,41] Infection rates may be lower when catheter care is provided by a specially trained team.[187] Transparent catheter site dressings should be changed every 5 to 7 days and site care performed with a chlorhexidine-based antiseptic; dressings should be changed immediately if visibly soiled, loose, or damp.[41] Recommended frequency of changes for gauze dressings is every 2 days. Catheter hubs repeatedly have been demonstrated to be common sites of colonization.[188] Thus the hub of the catheter should be cleansed each time it is accessed with either 70% ethanol, alcoholic chlorhexidine, or povidone-iodine,[41] although use of chlorhexidine for disinfection may have longer lasting residual activity.[189] Mechanical friction should be applied to the hub for no less than 5 seconds.[70] Administration sets need to be changed no more frequently than at 96-hour intervals,[41] unless blood- or lipid-containing solutions are administered, in which case tubing should be changed within 24 hours after the infusion is initiated.[167,190]

Antimicrobial-based preventive strategies for select populations or individuals at higher risk for CLABSI include antimicrobial lock therapy, use of antimicrobial-impregnated catheters, and antimicrobial-impregnated dressings. As described previously, antimicrobial "locks" involve use of supratherapeutic concentrations of an antimicrobial agent (e.g., antibiotic or 70% ethanol) that is confined to the catheter lumen while the CVC is idle. Numerous studies of antimicrobial lock therapy have shown significant reductions in CLABSI risk, including a recent meta-analysis of randomized clinical trials that demonstrated a 69% reduction in CLABSI rate among a variety of patient populations, including hemodialysis patients, adult and pediatric oncology patients, critically ill neonates, and patients receiving total parenteral nutrition.[191–195] This effect appears to be additive to traditional preventive measures. However, because of concerns regarding the emergence of antimicrobial resistance in exposed organisms, antimicrobial lock therapy is recommended in patients at highest risk, including those with long-term hemodialysis catheters, patients with limited venous access and history of recurrent CLABSI, and those at risk for severe sequelae from infection.[41]

Catheters that are coated or impregnated with antimicrobial or antiseptic agents, such as chlorhexidine–silver sulfadiazine[30] or minocycline-rifampin,[196] can decrease the risk for infection and have been shown to decrease hospital costs, despite the additional expense of these devices.[24] The anti-infective effect of these catheters, however, is not permanent and may be limited to a relatively short period after insertion; data are lacking on their efficacy for longer insertion times (e.g., ≥2 weeks).[73] Although the efficacy has not been widely demonstrated in children, data from observational studies suggest that impregnated or coated catheters are safe and may be effective in reducing CLABSI in pediatric ICU patients,[39,197–199a] including a single-center study that demonstrated that minocycline-rifampin–coated CVCs delayed the occurrence of infection in critically ill children.[34] Such catheters are approved by the FDA for use in patients weighing >3 kg and are recommended for clinical situations in which the incidence of CLABSI is high despite implementation of other preventive measures.[34,41,67]

Use of chlorhexidine-impregnated dressings also has been shown to be protective against CLABSI, including in a randomized trial in adult patients,[200] although it is unclear whether their use provides additional benefit if daily chlorhexidine bathing is performed. In a randomized study performed in children with cardiac disease, use of a chlorhexidine-impregnated dressing reduced the rate of catheter colonization but not of catheter-related BSI.[201] Luminal contamination may be reduced through use of closed catheter connection systems[202] or a self-disinfecting CVC hub (containing iodinated alcohol).[203–205] Use of a chlorhexidine-impregnated dressing is recommended for patients older than 2 months when CLABSI rates are not decreasing despite adherence to all preventive measures.[34,41]

There are few guidelines for outpatient management of vascular catheters, although most CLABSIs occur in hospital units outside of the ICU or in outpatients. Issues that require further study include the safety of bathing or swimming; the optimal frequency of dressing, cap, and tubing changes; and optimal care of the insertion site. One study suggested that children with subcutaneously implanted catheters who swim (while the catheter is not being accessed) are not at higher risk for infection.[206] Nevertheless, when patients are discharged with indwelling venous catheters, they and their caregivers should understand the need to protect the catheter and catheter site and avoid contamination with tap water.

Infections of Prosthetic Valves, Patches, and Vascular Grafts

Epidemiology and Pathogenesis

Prosthetic valve and patch infections are classified as *early* (occurring ≤60 days after implantation) or *late* (occurring >60 days after implantation). Agents causing early infection are presumed to have been introduced at the time of the surgery or soon thereafter (Box 100.7). *S. aureus* is the most common cause of prosthetic valve endocarditis and vascular graft infection, followed by CoNS.[12,207–209] Other pathogens are *Enterococcus* spp., *Corynebacterium* spp., fungi, and gram-negative enteric bacilli; and rarely *Mycoplasma hominis*, *Brucella melitensis*, *Legionella* spp., *Pasteurella multocida*, and *Kingella kingae*.[210–216]

Box 100.7

Routes of Infection in Prosthetic Valve Endocarditis

Early Infection

Inoculation during insertion

Seeding from catheter-associated bacteremia

Spread from infected wound

Late Infection

Hematogenous spread: bacteremia due to tooth/gum disease, surgical procedures, infection elsewhere

Bacteremia in patients with prosthetic valves often is related to medical devices, particularly vascular catheters; one third of infections are HAIs.[188] In a prospective study of patients with prosthetic valves and healthcare-associated BSI, 43% had endocarditis.[217] The rate of infection of prosthetic valves is 1% to 4% for early infection and about 1% annually for late infections (after the prosthesis has become endothelialized).[209,218] Reported rates of infection of vascular grafts range from 0.5% to 4%.[189] Grafts in the lower extremities, especially the groin, are more likely to become infected. Hemodialysis grafts and fistulas most often are infected with *S. aureus*. Infection with gram-negative bacilli or nontuberculous mycobacteria can be associated with improper sterilization of hemodialyzers.[219–223]

Clinical Manifestations and Laboratory Diagnosis

Patients with infected prosthetic valves or patches typically come to medical attention with fever. Hemodynamic changes can be present in patients infected with more virulent organisms (Box 100.8).[209] Valve ring abscesses can lead to perivalvular leakage. The leakage may be appreciated as a new murmur and can be complicated by congestive heart failure and rhythm disturbances, such as heart block. Late infections generally give rise to the usual signs and symptoms of subacute bacterial endocarditis but can be more acute and fulminant depending on the pathogen (e.g., *S. aureus*, *Streptococcus pyogenes*).

Box 100.8

Diagnosis of Prosthetic Valve Infection

Physical Findings

New murmur

Congestive heart failure

Arrhythmia

Skin lesions (Osler nodes, Janeway lesions)

Petechiae; splinter and subconjunctival hemorrhages

Laboratory Findings

Positive blood culture

Elevated C-reactive protein/erythrocyte sedimentation rate

Elevated white blood cell count

Microscopic hematuria

Echocardiogram

Cardiac failure/valve dysfunction

Vegetation

Blood cultures are essential to optimal management. Bacteremia generally is continuous; however, culture results can be negative because of prior exposure to antimicrobial therapy or the presence of a fastidious organism. Echocardiography is another key component of the evaluation of patients with suspected endocarditis.[209,224] In children, adequate imaging often can be achieved by transthoracic echocardiography. The sensitivity of transesophageal echocardiography, however, generally is greater than transthoracic studies.[225] A negative echocardiogram does not exclude endocarditis; negative studies can occur if vegetations are small or have already embolized, or if prosthetic material obscures or distorts the images.

Graft infection can manifest as local wound purulence, pseudoaneurysm at the graft-vessel anastomosis, hemorrhage, or thrombosis. Physical examination often identifies infection in superficially located grafts. Ultrasonography is useful to detect pseudoaneurysms and thromboses. Other studies, such as angiography, computed tomography, and magnetic resonance imaging, are occasionally needed to determine the extent of infection and the presence of complications.[219]

Management and Outcome

Antimicrobial therapy and surgery are the main therapeutic modalities for infections of prosthetic valves and patches. For both early and late infections, combination therapy using synergistic antimicrobial agents is recommended,[209,224] although the benefit of combination therapy remains unclear. Because CoNS almost always is resistant to β-lactam agents, vancomycin and an aminoglycoside plus rifampin often are used empirically until culture results are known. Consensus guidelines for the treatment and prevention of endocarditis for patients with prosthetic valves have been published.[209,226]

Surgical consultation is advisable, particularly for patients early in the course and with acute infection. The benefit of surgery over medical therapy in adults with prosthetic valve endocarditis has not been demonstrated clearly,[227] and large pediatric studies have not been performed. Indications for surgery early in the course of infection include hemodynamic instability, repeated major embolizations, inability to control infection, and relapse of infection. Indications for surgery later in the course of acute infection include new regurgitant murmur, moderate to severe heart failure, or a myocardial abscess unresponsive to medical therapy.[228–231] When surgery has been undertaken during acute infection, studies have demonstrated that infection of new valves implanted at this time is relatively uncommon.[207–209,232] A retrospective analysis of *S. aureus* prosthetic valve endocarditis revealed significantly lower mortality when valves were replaced during antimicrobial therapy.[233] Therapy for infected grafts often requires surgical resection or revision for cure.[219] Antimicrobial agents have limited penetration in areas with poor blood flow (i.e., a thrombosed graft).

The role of anticoagulation in infection of prosthetic valves or grafts is still debated. Most patients with prosthetic valves are treated with anticoagulants; discontinuation of this therapy is associated with a higher incidence of thrombosis and embolic phenomena.[208,209] The risk for death, however, from neurologic events is higher if anticoagulation is continued.[234]

Complications of intravascular infections include thrombosis, hemorrhage, embolic infarction and infection, graft dysfunction, heart failure, overwhelming infection, and death, with 1-year mortality rates of more than 30% in adults.[227] Prognosis of prosthetic valve endocarditis depends on the organism, the condition of the patient at the time of diagnosis, the rapidity and appropriateness of antimicrobial therapy, and the timely use of surgical intervention if appropriate.[209,218,224,232,235]

Prevention

Important measures to prevent infection of prosthetic valves and grafts include proper timing of surgical procedures (e.g., avoiding elective surgery in a patient with an intravascular device and an active distant infection), appropriate administration of periprocedural prophylactic antibiotics,[233] meticulous attention to surgical asepsis, and prompt removal of catheters and other potential infectious foci (Box 100.9). The common practice of continuing perioperative antimicrobial prophylaxis until catheters or drains are removed is inappropriate and may prevent the timely identification of pathogens in early prosthetic valve endocarditis.

Box 100.9

Prevention of Prosthetic Valve Infection

Use prophylactic perioperative antimicrobial agents at time of placement and subsequent dental/surgical procedures

Minimize intraoperative contamination

Remove catheters as soon as possible

Use meticulous wound care: handwashing, removal of necrotic tissue, avoidance of contamination

Minimize antimicrobial agents to maintain normal flora

Avoid antacids to diminish colonization of stomach and subsequent spread to lungs

Prevention of graft infection starts with meticulous attention to sterile technique at the time of implantation. Hemodialysis grafts are at risk for contamination and subsequent infection with each dialysis procedure, so good hygiene and care of the graft site with each access are essential.[218] Because *S. aureus* is by far the most common pathogen associated with dialysis grafts, attempts have been made to decrease patient colonization through the use of intranasal mupirocin or systemic rifampin and cloxacillin; these attempts have met with some success.[234,236–238]

If dialyzers are reused, strict adherence to sterilization and reuse protocols is crucial. The Association for the Advancement of Medical Instrumentation and the CDC recommend that hemodialysis fluids be monitored at least monthly with quantitative culture and endotoxin assay. Water used to prepare dialysate must have ≤200 CFU/mL in culture, and water used to reprocess hemodialyzers should have ≤200 CFU/mL in culture and <1 ng/mL of endotoxin on assay. Dialysate colony counts should be ≤2000 CFU/mL.[239]

Infections Associated With Pacemakers and Left Ventricular Assist Devices

Epidemiology and Pathogenesis

Temporary pacemaker wires, which generally are inserted percutaneously into the bloodstream, are associated with infection risks similar to those for vascular catheters. In addition, pacemaker wires typically are embedded into the myocardium, posing a risk for myocardial abscess. Permanent pacemakers consist of a battery, which is inserted into a soft tissue pocket, and wires that pass across tissue planes to reach the myocardium. During initial placement either the battery or wires can become contaminated.[240] Infection in children occurs in 1% to 8% of patients.[209] Although most infections are limited to the pocket site, roughly 10% of adult pacemaker infections result in endocarditis.[226]

Left ventricular assist devices (LVADs) consist of a pump with an inflow conduit from the left ventricular apex and an outflow conduit to the ascending aorta. Although original models used bioprosthetic valves to maintain unidirectional flow, newer continuous flow pumps do not require valves.[241] The pump is placed into a pocket formed in the lateral rectus sheath. A driveline, tunneled from the pump, connects to an external power source through an exit site on the lower abdominal wall. LVAD-related infection is a common complication, occurring in 25% to 70% of patients,[242–248] and can include local infection of the driveline or pocket as well as LVAD-related BSI with or without endocarditis.[244,249]

Clinical Manifestations and Laboratory Diagnosis

Signs of pacemaker infection include tenderness and erythema around the battery pocket, fever, and, occasionally, BSI.[250,251] Although most studies of pacemaker and LVAD infections focus on adults, pediatric case series suggest similar etiologies and outcomes of infection.[247] The most common organisms are CoNS (42%) and *S. aureus* (29%), although gram-negative enteric bacilli and yeast can be isolated.[226] Signs of LVAD driveline infection include localized purulent drainage from the abdominal exit site. Device pocket infection is characterized by tenderness and erythema around the pump pocket and purulence within the subcutaneous space. BSI can cause fever, chills, and other constitutional symptoms. The distribution of pathogens identified in LVAD infection is similar to that encountered in pacemaker infections,[242,243,246–248] although recent reports suggest that fungal infections may be becoming more common.[244] Diagnosis is made by culturing relevant purulent drainage and obtaining blood cultures.

Management and Outcome

Treatment of pacemaker infections depends on the extent of the infection.[226] Localized cellulitis without device involvement often can be managed with systemic antimicrobial therapy without removal of the pacemaker battery. Indications for removal and replacement of the wire include (1) valvular or lead endocarditis or sepsis; (2) pocket infection with abscess formation, device erosion, skin adherence, or chronic draining or recurrent sinus; or (3) occult BSI. The outcome depends on the site of infection, the pathogen, and the condition of the patient. Local infections usually resolve without sequelae; deeper infections are associated with greater morbidity and mortality.

LVAD infections are difficult to eradicate and are associated with significant mortality.[244,246–248] Evidence for optimal treatment for LVAD-associated infection is derived largely from single-center case series with almost entirely adults. Although the optimal duration of therapy for LVAD-associated infection is unknown, continuous antimicrobial therapy before, during, and beyond transplantation may be required. Intraoperative debridement or, in rare cases, device removal and exchange may be required.[246,248,252] The results of a large single-center study suggested that continuous antimicrobial therapy is associated with fewer relapses than a limited course of therapy.[243] The potential benefits of prolonged antimicrobial therapy, however, must be balanced against the risk for developing antimicrobial resistance.

Prevention

Evidence-based data on the efficacy of measures to prevent infections in patients with pacemakers and LVADs are lacking. Antibiotic prophylaxis recommendations for pacemakers and

LVADs are modeled after those used to prevent surgical site infection.[226,253] For LVAD drivelines, exit site care usually consists of daily sterile cleansing with povidone-iodine and isopropyl alcohol, dilute hydrogen peroxide, or chlorhexidine and placement of an occlusive dressing.[243] Although fungal LVAD infections are associated with a worse prognosis than bacterial infections, systemic antifungal prophylaxis does not appear to prevent fungal infection.[244]

Infections of Central Nervous System Devices

Epidemiology and Pathogenesis

Central nervous system (CNS) devices include cerebrospinal fluid (CSF) shunts, subarachnoid screws and bolts, and subdural catheters.[254] Infections usually are caused by skin flora introduced during surgical insertion. Skin-associated tract infections and ascending infection can occur postoperatively in patients with ventriculoperitoneal (VP) shunts.[255] The latter develops when the distal end of a VP shunt penetrates the bowel (or is surrounded by a collection of contaminated mesenteric/peritoneal fluid, i.e., “CSFoma”) and typically are polymicrobial. Rarely, the VP catheter tip perforates the genitourinary system and becomes contaminated with local flora. Ventriculostomy catheters exit percutaneously to an external monitoring system and can become contaminated during placement or manipulation.[256,257] Moreover, skin flora can ascend from the exit site along the catheter and into the ventricle. Subcutaneous reservoirs can be contaminated during placement or subsequent access.

Infection rates for VP shunts range from 3% to 35%.[1,258–263] In general, rates are higher for second procedures (especially for replacement of an infected shunt, although the causative organisms may be dissimilar),[254] among those with perioperative CSF leak or myelomeningocele, and for shunts placed for hydrocephalus due to intraventricular hemorrhage fluid shunt infections in children.[263–265] Infections rates generally are higher in children than adults.[266] Most infections occur within 2 months of shunt placement.[267] In a study from 41 free-standing children's hospitals, the rates of shunt infection at 24 months were 11.7% per patient and 7.2% per procedure, although rates varied widely across institutions.[268] A follow-up analysis revealed a reinfection rate of 14.8%, most of which occurred within the first 2 months after reinsertion.[269] One study found that rates of infection were highest in July, possibly correlating with the arrival of new neurosurgical fellows in hospital programs.[260] As with other indwelling catheters, the rate of infection depends on the duration of catheterization.[270] Infection rates have been reported to be approximately 20% to 25% for subcutaneous reservoirs[270] and 10% for percutaneous ventriculostomies.

Clinical Manifestations and Laboratory Diagnosis

Catheter malfunction is the most common manifestation of infection. For shunts, malfunction produces signs of increased intracranial pressure (i.e., headache, vomiting, irritability, or mental status changes). Fever is usually but not always present.[254,256] Abdominal symptoms can predominate when the gastrointestinal tract is the source of shunt infection or if primary ventricular infection causes clinical peritonitis. Seizure occasionally is a presenting sign. Shunt malfunction due to occlusion or disconnection is the major alternative diagnosis. A malfunctioning shunt should be considered infected until proven otherwise, even in the absence of systemic manifestations and CSF pleocytosis.[256] Up to 30% of malfunctioning shunts are ultimately proven infected.[260]

Most infections are caused by CoNS and other skin flora; gram-negative bacteria account for about 20%.[256–260,271,272] Skin flora, including *Corynebacterium* spp. and *Propionibacterium acnes*, can cause particularly indolent infections. Fungal infections most commonly are caused by *Candida* spp. and occur most commonly in prematurely born infants.[273]

Diagnosis requires examination and culture of ventricular fluid; lumbar CSF is not sufficient.[274] Pleocytosis is typical but can range from none to thousands of cells per cubic millimeter.[5,258,263,274] Elevated ventricular fluid protein is more common than abnormal glucose concentration. Clinical and laboratory findings often are subtle in infections due to CoNS. Blood culture results usually are positive with ventriculoatrial shunt infection; likewise, pleural fluid culture can be positive in ventriculopleural shunt infections, and peritoneal fluid in VP shunt infections. Blood culture is rarely positive in VP shunt infection. Abdominal complications of VP shunts, including formation of pseudocyst (CSFoma), are best diagnosed with ultrasonography or computed tomography.[275,276] Lumbar puncture for CSF examination should be performed for a child with a lumboperitoneal shunt, or a VP shunt when the diagnosis of meningitis is suspected and ventricular shunt fluid is normal.

Management and Outcome

Treatment includes antimicrobial therapy and surgery.[254,256,260] Cure with systemic antimicrobial therapy alone is unusual. A common approach to treatment includes (1) removing the ventriculostomy or shunt or externalizing the peritoneal end of the shunt; (2) beginning systemic antimicrobial therapy; and (3) sampling ventricular fluid daily. Empiric therapy consists of an antistaphylococcal agent with adequate CSF penetration (nafcillin, oxacillin, or vancomycin); if abdominal signs are present or if a gram-negative infection is suspected, a broad-spectrum cephalosporin, such as cefotaxime, ceftriaxone, or cefepime, plus an aminoglycoside is added. Definitive therapy is based on susceptibility test results of isolates and ability of the antimicrobial agent to penetrate the CSF. Rifampin may be useful in combination therapy for patients with infection due to staphylococci, especially when the shunt cannot be removed. If the infection does not resolve promptly, antimicrobial agents also can be administered intraventricularly.[277–279]

Cultures should be repeated frequently to ensure that the infection is controlled and to use time-to-sterilization as a basis for duration of therapy. The system is replaced after the infection is fully controlled and cultures are negative. Limited data inform duration of antimicrobial therapy or optimal timing for shunt replacement.[256,257,280] Some experts recommend 7 to 10 days of antimicrobial therapy after sterilizing CSF, with extension to 10 to 14 days for more virulent pathogens such as *S. aureus*.[279,281] Timing of shunt replacement must balance the risks for superinfection associated with prolonged externalization against the risk for premature internalization with contamination of a new system.

The major complication of ventriculitis is brain injury. Studies of children with myelomeningocele reveal that the number of shunt infections is a major determinant of low intelligence.[282] The prognosis for ventriculitis depends on the virulence of the pathogen and condition of the underlying host. Infections caused by slime-producing strains of CoNS may be more difficult to cure.[283] Infection in the immunocompromised host is more likely to result in morbidity or mortality. Complications of peritonitis include adhesions, bowel obstruction, and loss of fluid-absorptive capacity. Respiratory distress due to pleural effusion or infection can complicate infections of ventriculopleural shunts (Box 100.10). Ventriculoatrial infection can lead to endocarditis and immune complex-related glomerulonephritis.

Box 100.10

Complications of Central Nervous System Devices

All Shunts

Ventriculitis: loss of neurons

Ventriculoperitoneal Shunts

Peritonitis: bowel obstruction, abdominal pseudocyst ("CSFoma"), loss of absorptive surface

Ventriculopleural Shunts

Pleural effusion, empyema

Ventriculoatrial Shunts

Bacteremia, endocarditis, nephritis

CSF, cerebrospinal fluid.

Prevention

Prevention of infection depends on the appropriateness of antimicrobial prophylaxis as well as meticulous sterile technique during device placement and with each sampling of CSF. Shaving the scalp over the shunt button before CSF collection damages the skin and increases the risk for infection at subsequent samplings; if hair removal is required, clipping should be performed. Although some individual studies of antimicrobial prophylaxis have failed to show a significant effect on infection rate, a meta-analysis suggests that perioperative prophylaxis reduces the incidence of shunt infection.[284] The optimal antimicrobial regimen remains unclear.[259,285,286] Administration of antimicrobial agents for the duration of continuous intracranial pressure monitoring is not appropriate.[287]

Prophylaxis for CNS devices should be limited to the perioperative period. Catheters and shunts impregnated with antimicrobial agents, such as rifampin and clindamycin, have been shown in vitro and in animal models to inhibit bacterial colonization.[288,289] Small clinical trials in adults[290–292] and children[293,294] and a meta-analysis[284] also support the efficacy of antimicrobial catheters for infection prevention.

Similar to prevention strategies for other device-related infections, the use of a standardized prevention protocol was recently evaluated among a collaborative of pediatric neurosurgical centers in the management of hydrocephalus.[295] Elements of the protocol included posting signs on the door to limit traffic during the procedure, positioning the head away from the main operating room door, providing specific guidance around perioperative prophylaxis and timing, and using an alcoholic chlorhexidine solution for skin antisepsis. The network infection rate decreased from 8.8% to 5.7% over a 6-month period with implementation of the protocol across centers; compliance with the protocol was reported at 74% overall but improved over the study period.

Infections Associated With Peritoneal Catheters

Epidemiology and Pathogenesis

Peritoneal catheters are most often inserted for continuous ambulatory peritoneal dialysis (CAPD). Peritoneal dialysis removes complement and immunoglobulins and thus impairs host defenses.[296,297] In addition, the low pH of dialysate inhibits neutrophil function.[297] Peritoneal catheter-associated infections include catheter exit site and tunnel infections as well as peritonitis; the incidence of peritonitis in children is approximately 0.67 episodes per patient-year.[298,299] Longer duration of dialysis therapy, younger age, and decreased serum concentrations of immunoglobulin G are associated with a higher incidence of peritonitis.[299,300]

Organisms can enter the peritoneum during placement and subsequent manipulation of the catheter, through intrinsically or extrinsically contaminated peritoneal dialysis fluid, or after perforation of the bowel by the catheter tip.[301] Hematogenous seeding, ascending infection through the fallopian tubes, and transmural migration of bacteria across the bowel wall are less common routes of infection.[296] The most common organisms are those that colonize the skin around the catheter insertion site and that may enter the peritoneum through the catheter tract: *S. aureus* and CoNS, which are isolated in 50% to 60% of infections; gram-negative enteric bacilli in 20% to 30%; and, less frequently, *Candida* spp., nontuberculous mycobacteria, molds, and *Nocardia* spp.[296,300,302,303]

Clinical Manifestations and Laboratory Diagnosis

Clinical findings in peritonitis include fever, abdominal tenderness, and cloudy dialysate. Presentations range from subtle pain to sepsis syndrome.[301] The differential diagnosis includes chemical peritonitis, eosinophilic peritonitis, hemoperitoneum, chylous ascites, and (rarely) malignancy.[299] Examination of the dialysate fluid usually reveals pleocytosis. Cell counts vary, depending on fluid dwell time and the causal pathogen, but leukocyte counts of >100 cells/mm^3 with neutrophil counts of >50% suggest infection.[296,304,305] There is no consensus on the optimal method to culture fluid. Consensus guidelines recommend centrifugation of a large volume (50 mL) of fluid for inoculation of blood culture media.[296,304–306] Exit site infection causes pericathether swelling, erythema, and tenderness localized to the catheter insertion site, whereas a tunnel infection causes these same signs and symptoms along the subcutaneous portion of the catheter.[305] Ultrasonography of the catheter tunnel can be useful in diagnosing tunnel site infection (particularly when exit site infection is apparent or in the setting of peritonitis) and after response to therapy.[307–311]

Management and Outcome

Exit site infections often respond to local therapy and oral antimicrobial therapy for 2 to 3 weeks depending on the organism isolated.[305] Infections of the tunnel often require catheter removal.[296] Peritonitis is usually managed with intraperitoneal antimicrobial therapy and continuous dialysis.[301] Most patients with CAPD-associated peritonitis can be treated in the ambulatory setting. If the patient is systemically ill or if attempts to eradicate the bacteria fail, hospital admission and systemic antimicrobial therapy are warranted, and catheter removal should be considered. Catheter removal is essential for cure of fungal infection[303] and often is necessary for enterococcal and *Pseudomonas* infections.[302] Several reports indicate that simultaneous removal and replacement of the catheter is successful in selected instances,[310–312] particularly when infection is caused by staphylococci, when the tunnel is involved, or in cases of recurrent peritonitis that clears intermittently with treatment.[305] This approach is less likely to be effective in infections due to gram-negative organisms or fungi, or if there is ongoing inflammation between episodes of recurrent peritonitis.[312] There are no controlled studies on optimal duration of therapy; the recommended course for children is 2 weeks, extended to 3 weeks for *S. aureus*.[313] Complications include intra-abdominal abscess formation, adhesions with subsequent bowel obstruction, and impairment of the diffusable peritoneal surface available for dialysis.

Prevention

Staphylococcal carriage predisposes to peritonitis. Eradication of nasal or skin carriage with antistaphylococcal agents has been shown to decrease the incidence of peritonitis due to *S. aureus*.[314–317] Systemic administration of rifampin, combined with an antistaphylococcal agent for 7 days, appears to be most effective.[314] Extensive guidelines for the prevention of infections associated with peritoneal dialysis in children have been published and include a standardized approach to training of nursing staff; catheter type, placement, and connection; exit sit care; and antimicrobial prophylaxis for catheter placement and in high-risk exposures.[305]

Infections of Orthopedic Devices

Epidemiology and Pathogenesis

Prosthetic joints are used less commonly in children than in adults, but pins, medullary nails, and rods are commonly placed in children for stabilization of fractures and during corrective surgery. Infection is a major complication of orthopedic devices[318,319]; incidence varies with type of procedure and patient population.[1] Infection after pediatric spinal fusion procedures varies by the underlying diagnosis: correction of adolescent idiopathic scoliosis is complicated by surgical site infection only 1% to 2% of cases, whereas infection rates for nonidiopathic scoliosis can be >10%.[320] For hip and knee replacements in adults, cumulative incidence of infection is roughly 1% to 2% over the life of the prosthesis but varies depending on the type of prosthesis or whether it is a primary implant or revision.[321] Risk for infection is higher in the presence of underlying malignancy; in a surgical site infection not involving the prosthesis; with a National Nosocomial Infections Surveillance System surgical patient risk index of >1[322]; and after surgery related to a previously infected site.[323,324] Pin site infections are common because the pin track creates a direct pathway for skin flora and contaminating organisms to reach soft tissues and bone. Infection risk depends on the mode and site of injury, amount of associated soft tissue injury, and time before pin removal. Solid medullary nails are associated with lower infection risk than hollow nails.[325]

Most infections are caused by CoNS and *S. aureus*. Other gram-positive cocci, such as group A streptococci, oral streptococci, and enterococci, as well as gram-negative enteric bacilli, are occasionally involved. Anaerobic bacteria account for <10% of infections.

Organisms gain access to the joint and bone at the time of implantation and later by spread from contiguous infections or (less commonly) by hematogenous seeding.[318,319]

Clinical Manifestations and Laboratory Diagnosis

Clinical manifestations of implanted orthopedic device–associated infection frequently are subtle. Findings include pain, wound dehiscence, or loosening or malfunction of prosthetic joints. With pin-related infections, there is usually purulence at the skin exit site, but the depth of involvement is difficult to determine; infection can extend to the intramedullary cavity.[326] Toxic shock has been reported as a complication of pin site infection,[327] as has brain abscess secondary to a halo orthosis pin site infection.[328]

The diagnostic utility of most radiographic techniques in pin, nail, and joint infection is limited because the appearance of infection mimics that of healing bone. For prosthetic joints, radiographs sometimes are helpful; periosteal reaction occurs with infection but also can occur with normal healing. An area of radiolucency surrounded by a sclerotic edge is suggestive of infection.[329] Radionuclide scans are sensitive but not specific and do not reliably differentiate infection from fracture and healing bone.[330,331] Computed tomography and magnetic resonance imaging are rarely helpful because the device often causes artifacts, obscuring the area of interest.[318] Assessment of inflammatory markers, including erythrocyte sedimentation rate and C-reactive protein, may help guide diagnosis and treatment.

Culture of superficial drainage from pin sites or draining sinuses can yield colonizing or contaminating organisms rather than the true etiologic agent. Direct sampling of the bone or joint for histologic examination and culture usually is required for definitive diagnosis.[319] Intraoperative specimens evaluated by frozen-section examination are useful in excluding active infection during surgery to revise loosened prostheses.[332]

Management and Outcome

The treatment of infections associated with surgical implants is challenging.[333] Therapy for superficial pin track infections involves pin removal and prolonged antimicrobial therapy. For infected rods and joints, removing the device offers the best chance of cure but is complicated by prolonged disability and deformity. Often, a two-step approach is used, in which the infection is first brought under control with systemic antimicrobial therapy and the device and all devitalized tissue and cement are removed. At a later date, the device is replaced.[334,335] There is no consensus regarding the ideal interval before replacement.

If removal of the device is not feasible, a combination of antimicrobial therapy and debridement can be attempted. Although retaining the prosthesis had historically met with limited success,[336,337] some studies of adults with infected hip and knee prostheses demonstrated successful treatment with prolonged oral antimicrobial therapy, primarily with combinations of ciprofloxacin and rifampin and retention of the prosthesis after initial debridement.[338,339]

Antimicrobial therapy for infected orthopedic devices typically is prolonged. For staphylococcal infections, the combination of a β-lactam or fluoroquinolone plus rifampin may be considered if the organism is susceptible and the device cannot be removed.[340] For cases in which the device is left in place, vacuum device to enhance blood flow, and long-term suppressive therapy may be warranted. If there are large tissue defects over the involved area, skin and muscle flaps may help by providing a vascular source to enhance host defenses and improve antimicrobial delivery.[341]

Prevention

Methods designed to decrease contamination of the operative field during implantation of orthopedic devices have been studied, including increasing the number of operating room air exchanges as well as use of high-efficiency particulate air filters, laminar flow systems, and special barrier suits for surgeons.[342] A large prospective study involving >7000 patients showed no difference in rates of infection between the use of conventional operating suites and laminar flow rooms,[319] and more recent analyses suggest that laminar flow may increase the rate of surgical site infection after some orthopedic implantation procedures.[343]

Perioperative prophylaxis, primarily with intravenous antistaphylococcal agents, is beneficial. Administration of prophylactic agents should be confined to the immediate perioperative period (i.e., from just before the procedure to 24 hours afterward). The appropriate drug, dose, and timing of antimicrobial prophylaxis before orthopedic implantation is critical,[344] and guidelines for perioperative prophylaxis of pediatric orthopedic procedures have been published.[345] The clinical efficacy of dipping implants in antimicrobial solutions, antimicrobial coating of implants, use of antimicrobial carriers (e.g., cements, beads), or topical application of antimicrobials to the surgical bed before closure (e.g., vancomycin "powder") has not been established.[345–349] Antimicrobial prophylaxis in persons with orthopedic implants who undergo dental or surgical procedures typically is not recommended.[350,351]

Infection of Urinary Catheters

Epidemiology and Pathogenesis

The literature describing catheter-associated urinary tract infections (CAUTIs) in children largely is limited by two factors: (1) studies often fail to distinguish symptomatic from asymptomatic infections (i.e., catheter-associated bacteriuria from CAUTI), and (2) data describing epidemiology and strategies for the management and prevention of infections are limited. Despite these limitations, many principles of adult CAUTI are reasonably adapted to pediatrics.

Infection is the most common complication of urinary catheterization,[352,353] and CAUTI is the most common HAI in adults worldwide.[354] CAUTI makes up a much smaller proportion of device-related HAI in pediatric patients, likely owing to differences in urinary tract catheterization between adults and children. However, data from the CDC NHSN show that pooled mean rates of CAUTI are similar between adult and pediatric ICUs.[32] Isolated cystitis occurs most commonly, but pyelonephritis and secondary BSI also can develop. Limited data exist on the epidemiology of pediatric CAUTI. A recent retrospective analysis of CAUTI in a tertiary care children's hospital found that >80% of CAUTIs were identified in critically ill children and 75% were in females; nearly all patients had at least one chronic underlying condition, and approximately one third had either an anatomic or functional abnormality of the genitourinary tract.[355]

Microbial colonization of the urine is the first step in the pathogenesis of CAUTI, although many chronically catheterized patients may have evidence of bladder colonization without clinical evidence of infection. Pathogens can be introduced during catheter insertion, by ascending from the perineum along the external surface of the catheter, or intraluminally through contamination of the collecting tube or drainage bag.[356,357] After insertion, microbes begin to adhere along the internal and external surfaces of the catheter, leading to the rapid formation of polymicrobic biofilms that migrate to the bladder within 1 to 3 days.[354,358,359] Duration of catheterization is the most important risk factor for CAUTI.[353] The incidence of catheter-associated bacteriuria is estimated at 3% to 8% per day[354]; estimates are lower in the presence of a closed drainage system and higher with open drainage, when diarrhea is present, and when there is diminished urine flow or urinary stasis (as occurs with ureteral reflux, bladder diverticula, and stenosis of the urethra).[1,116,357–361]

The most common organisms that cause CAUTIs are members of the perineal flora.[44] Infections in patients with short-term indwelling catheters (<30 days) are typically caused by a single organism, whereas infections in patients with long-term catheters (>30 days) are more often polymicrobial.[314] *E. coli* is most commonly identified; other enteric gram-negative bacilli, *Enterococcus* spp., and *Candida* spp. also are frequent. Patients receiving antimicrobial agents are at high risk for infection due to resistant bacteria and fungi.[357,362]

Clinical Manifestations and Laboratory Diagnosis

Bacteriuria in patients with indwelling urinary catheters typically is asymptomatic.[363] Signs and symptoms of CAUTI can be challenging to identify because many catheterized patients do not manifest typical symptoms of UTI, such as urgency, frequency, and dysuria. Fever is often the most commonly identified sign. Other symptoms can include enuresis and cloudy or foul-smelling urine. Urinalysis and culture are useful to confirm infection. Urinalysis can reveal pyuria, but pyuria alone is not diagnostic of infection in a catheterized patient, particularly those with long-term indwelling catheters. Diagnosis of CAUTI is established by isolation of organisms with colony counts of $>10^5$ CFU/mL from a urine specimen that is obtained aseptically from the catheter.

Management and Outcome

Therapy for bacteriuria and infection should include removal of the catheter if possible. If the catheter remains in place, infection often persists despite appropriate antimicrobial treatment or recurs immediately after cessation of therapy. The need for antimicrobial therapy for bacteriuria or cystitis is debatable because infection often resolves spontaneously with removal of the catheter.[357] For complicating pyelonephritis and BSI, systemic therapy is necessary; the optimal duration is unclear.

The major complications of CAUTI are pyelonephritis, renal damage,[360] and BSI.[360,364] It is important to exclude UTI before major surgical interventions in catheterized patients. Prognosis is related to extent of the infection, the pathogen involved, and underlying host factors.

Prevention

Detailed guidelines for the prevention of CAUTI in acute care hospitals have been published and recently updated.[353] Many of these strategies have been incorporated into CAUTI prevention bundles that include standardized training and catheter insertion and maintenance practices; use of a CAUTI prevention bundle was recently associated with a significant reduction in CAUTI rates in a tertiary care children's hospital.[355] Important strategies to prevent CAUTI include (1) limiting catheterization to those for whom it is medically necessary; (2) using aseptic technique during catheter insertion; (3) properly securing the catheter and maintaining a sterile, continuously closed drainage system with unobstructed urine flow; and (4) removing the catheter as soon as possible. Using collection tubing that is free of kinks or dependent loops and positioning the collecting system below the level of the bladder avoid bladder urinary stasis or reflux.[23,353] In general, applying creams or attempting to wash the perineum raises the risk for UTI, probably because of movement of the catheter and an increase in introduction of perineal flora along the catheter and into the bladder.[365]

Catheters commonly are "forgotten" and left in place for too long. One study of adult medical inpatients revealed that clinicians were unaware that their patients had a catheter 28% of the time.[366]

Prophylactic antimicrobial therapy has been demonstrated to provide brief protection against bacteriuria[367]; however, few guidelines recommend this strategy because the risk for progression from asymptomatic bacteriuria to UTI remains low for most patients.[354] In addition, prolonged antimicrobial therapy is not protective and often is harmful because of the promotion of antimicrobial resistance and development of *Clostridium difficile* infection.[356]

Clean intermittent catheterization is preferred to indwelling catheterization in children with neurogenic bladder.[368] The abdominal Credé method does not empty the bladder and may increase the risk for infection.[19,356,369] Antiseptic-impregnated catheters have been shown to delay the onset of bacteriuria, but few studies have examined cost versus benefit and the risk for emerging resistant organisms associated with the use of these catheters.[370]

Infections in Patients With Deficient Defenses

OUTLINE

101 Evaluation of the Child With Suspected Immunodeficiency
102 Infectious Complications of Antibody Deficiency
103 Complement in Control of Infectious Agents
104 Infectious Complications of Dysfunction or Deficiency of Polymorphonuclear and Mononuclear Phagocytes
105 Infectious Complications of Cell-Mediated Immunity Other Than AIDS Primary Immunodeficiencies
106 Infectious Complications in Special Hosts
107 Infections Related to Biologic Modifier Therapy
108 Infectious Complications of Corticosteroid Therapy

101

Evaluation of the Child With Suspected Immunodeficiency

E. Stephen Buescher

Although primary immunodeficiency disorders are uncommon, referral for evaluation of these conditions in children with frequent infections is common. Epidemiologic studies show that children aged <2 years have an average of 5 to 6 acute respiratory tract illnesses per year, with a range up of to 11 or 12 per year.[1,2] Infections such as otitis media and gastroenteritis occur with similar frequencies in children <2 years of age, with up to 14 episodes per year at the far end of the normal spectrum.[3] Attendance at group childcare and exposure to secondhand smoke further increase frequency of these infections.[4] An approach that includes a carefully obtained history, a thorough physical examination, and selected laboratory tests often is required to differentiate the uncommon, immunologically abnormal child who requires more extensive evaluation from the common, “normal but unlucky” child.[5] Because normal children can experience large numbers of infections, criteria other than the number of illnesses should be considered. These include (1) a history of documented, deep infections at multiple sites; (2) abnormal growth or development; (3) abnormal morphology or physiology between infections; or (4) a family history of immunodeficiency. Further investigation is warranted in children with one or more of these characteristics and focuses on categorizing patients as to the likely cause for their recurrent infections.

Anatomic and Physiologic Abnormalities

A variety of anatomic abnormalities can alter natural host defenses and predispose a child to recurrent infections (Table 101.1). Anatomy-related infections often localize with recurrent infections at or near the site of the abnormality. In instances of congenital malformation, infections usually begin during infancy. Compared with the incidence of primary immunodeficiency disorders, congenital malformation as a cause of recurrent infections is common.

TABLE 101.1

Anatomic and Physiologic Abnormalities That Predispose to Recurrent Infections

Type of Infection	Predisposing Abnormality
Bloodstream infection	Asplenia
	Cardiac valve abnormality
	Intravascular cannula or thrombus
	Neutropenia
Bone infection	Foreign body
	Orthopedic device
Meningitis	Cochlear implant
	Dura mater (meningeal) defect
	Midline dermal sinus
	Mondini defect of inner ear
	Neuroenteric fistula
	Occult skull fracture
	Ventricular cannula
Pneumonia	Abnormal cough reflex
	Atelectasis
	Bronchiectasis
	Endotracheal intubation
	Extrinsic airway compression
	Foreign body
	Gastroesophageal reflux

	Polyps
	Pulmonary cyst, fistula
	Pulmonary sequestration
	Tracheal web
	Tracheoesophageal fistula
	Tracheomalacia
	Tracheostomy
	Vascular ring
Soft tissue infection	Diminished sensation
	Foreign body
	Lymphedema
	Thermal injury
Urinary tract infection	Genitourinary tract duplication, cyst, fistula, or obstruction
	Nephrostomy
	Urinary catheter
	Vesicostomy

Underlying Conditions

The presence of underlying conditions, either natural or iatrogenic, can alter host defenses and predispose to recurrent infections or may be associated with an immunodeficiency (Box 101.1). In addition to the primary immunodeficiency syndromes, recurrent infections occur in more than 100 other syndromes, which include growth deficiencies, specific organ system dysfunctions, inborn errors of metabolism, and miscellaneous and chromosomal anomalies.[6] Some underlying conditions only become serious diagnostic considerations when specific data are obtained during a detailed history. Some conditions are suspected when constellations of noninfectious signs and symptoms are revealed by history and physical examination. Recurrent infections associated with underlying conditions either can be localized or disseminated and may or may not respond well even when appropriate treatment is given. Compared with the incidence of primary immunodeficiency disorders, this category of causes of recurrent infections also is common.

Box 101.1

Underlying Conditions That Can Predispose to Recurrent Infections

Asplenia syndromes/conditions

Asthma

Bone marrow and solid-organ transplantation

Chemotherapy

Collagen vascular diseases

Congenital malformation

Corticosteroid therapy

Cystic fibrosis

Dermatologic syndrome with immunodeficiency

Diabetes mellitus

Down syndrome

Drug-induced cytopenia

Galactosemia

Gastrointestinal tract syndrome with immunodeficiency

Genetic/metabolic conditions

Glycogen storage disease type IB

Growth deficiency/immunodeficiency syndrome

Hematopoietic/immunologic conditions

Hemoglobinopathy

Ichthyosis

Immunosuppression

Isovaleric acidemia

Lymphohematopoietic malignancy

Malnutrition

α-Mannosidosis

Methylmalonic aciduria

Mucolipidosis II

Myelokathexis (WHIM syndrome)

Myotonic dystrophy

Nephrotic syndrome

Neurologic syndrome with immunodeficiency

Newborn state

Nutritional conditions

Orotic aciduria

Prematurity

Propionic acidemia

Protein-losing enteropathy

Radiation therapy

Renal conditions

Renal failure

Sarcoidosis

Tumor necrosis factor antagonist therapy

Werdnig-Hoffmann disease

WHIM (warts, hypogammaglobulinemia, infections, myelokathexis)

Primary Immunodeficiency Disorders

Recurrent infections due to primary immunodeficiency disorders are rare in the general population and are relatively rare compared with other causes of recurrent infection (Table 101.2). Common characteristics in children with primary immunodeficiency disorders are shown in Box 101.2.

TABLE 101.2

Estimated Frequencies of Selected Chronic Underlying Illnesses, Primary Immunodeficiency Disorders, and HIV Infection

Condition	Frequency
Asthma[26]	1 in 26
IgA deficiency	1 in 500 to 700
Diabetes mellitus[26]	1 in 556
HIV infection	1 in 1000
Sickle cell disease[26]	1 in 2200
Cystic fibrosis[27]	1 in 2500
Acute lymphocytic leukemia[26]	1 in 9000
Phenylketonuria[26]	1 in 10,000
Agammaglobulinemia[26]	1 in 50,000 to 100,000
Severe combined immunodeficiency	1 in 100,000 to 500,000
Chronic granulomatous disease[28]	1 in 255,000

HIV, human immunodeficiency virus; IgA, immunoglobulin A.

Box 101.2

Characteristics of Children Wth Primary Immunodeficiency Disorders

Infectious symptoms often begin in first days to weeks of life

Therapeutic response is slow despite identification of a pathogen and administration of appropriate antimicrobial therapy

Infection is suppressed rather than eradicated by appropriate therapy

Common organisms cause severe manifestations or recurrent infection

Unusual (sometimes sentinel) or "nonpathogenic" organisms cause infections

Growth and development are delayed

Multiple infections occur simultaneously

Infection with common organisms leads to unexpected complications

The relative frequency of primary immunodeficiency disorders is shown in Table 101.3.[7,8] The list of recognized immunodeficiency conditions is ever-expanding, and the component due to recognized disorders of the innate immune system is growing.[8] The International Union of Immunological Societies frequently publishes updates on the classification of primary immunodeficiencies, which include names of conditions, presumed pathogenesis, genetics, inheritance, immunologic parameters, associated features, and Online Mendelian Inheritance in Man (OMIM) reference numbers.[9] More than 250 conditions presently are identified.[9,10] Some are well characterized, their pathologic mechanisms are understood, and numerous affected patients have been described (e.g., chronic granulomatous disease, X-linked severe combined immunodeficiency syndrome, X-linked agammaglobulinemia, leukocyte adhesive deficiency type I, and adenosine deaminase deficiency).[11–15] Other conditions remain incompletely characterized, are poorly understood, or have been observed in so few patients that they have not been studied extensively (e.g., lazy leukocyte syndrome, generalized pustular psoriasis, reticular dysgenesis).[16–18]

TABLE 101.3

Relative Frequency of Primary Immunodeficiency Disorders

Factors	Percentage
B lymphocytes	50–70
T lymphocytes	20–30
T and B lymphocytes	10–15
Phagocytic cells	15–20
Complement	2–5
Other innate immunity factors	<1

Clinical Approach to the Child With

Recurrent Infections

History

A detailed history is the most powerful evaluation tool and should gather information using all available sources, including medical records, parent or patient interviews, radiographs, and laboratory test results. Information is assembled into a chronology of data and events to determine whether episodes of illness have been characterized well enough to confirm that the patient truly has had recurrent infections. Additional important considerations are whether treatment of infectious episodes was appropriate, response to treatment was as expected, or other explanations exist (e.g., fever from inflammatory rather than infectious disease).

Medical History

A description of each infectious episode is obtained, specifically: (1) date, duration, and site of infection; (2) how the diagnosis was established (i.e., specific cultures and diagnostic tests performed and their results); (3) severity of the episode (shock, tissue destruction, ventilator support, end-organ damage); (4) what treatment (need for parenteral or prolonged) was used and responses to specific treatments; (5) need for surgical intervention and quality of wound healing; and (6) temporal relationships to previous episodes. This level of detail often necessitates a prolonged interview but is crucial for establishing whether an immunodeficiency is likely. Additional helpful details of the patient's history include immunizations administered and any clinical illnesses associated with them, pattern of growth and development, medications given (including long-term antibiotic use) and their effect on course of disease, compliance with treatments, presence of conditions that can predispose to or masquerade as infections, unusual blood phenotypes (e.g., McLeod phenotype in chronic granulomatous disease, Bombay phenotype in leukocyte adhesion deficiency type II), and healing pattern after skin and soft tissue infection, injuries, or surgery. If infections have been localized around an anatomic site, details should be obtained to focus on foreign body aspiration, injuries or surgery at the site, medical problems involving the site, and timing of onset of infections relative to other events.

Historical details that decrease concern for a primary immunodeficiency are rapid responses to appropriate therapy, rapid resolution (vs. suppression) of infected foci, healing without scarring, and inability to document infection. Details that are difficult to assess are poorly documented "infections," "infections" in the presence of allergic inflammation, and infections occurring in association with underlying conditions.

The category of microorganisms (and certain sentinel organisms) causing infections can suggest specific disorders (Table 101.4). Recurrent infections with extracellular, encapsulated microorganisms or chronic sinopulmonary infections frequently occur in people with asplenia, antibody deficiency conditions, or pattern recognition molecule (e.g., mannose-binding lectin or toll-like receptor) dysfunction. Deep fungal infections, multiple liver abscesses, or osteomyelitis suggests a phagocytic cell disorder. Recurrent infections accompanied by autoimmune symptoms or recurrent infections with *Neisseria meningitidis* suggest complement deficiencies. Recurrent infections due to opportunistic viral, protozoal, bacterial, mycobacterial, or fungal agents suggest T-lymphocyte deficiency. Unusual susceptibility to human papillomavirus infections occurs in WHIM (warts, hypogammaglobulinemia, infections, myelokathexis) syndrome and severe and disseminated mycobacterial infections are seen in defects related to interferon γ production and signaling.

TABLE 101.4

Sentinel Pathogens of Infections and Associated Conditions

Infectious Agent	**Condition**
Mucoid *Pseudomonas aeruginosa*	Cystic fibrosis
Nocardia spp., *Aspergillus* spp.	Chronic granulomatous disease
Burkholderia cepacia pneumonia	Chronic granulomatous disease, cystic fibrosis
Recurrent *Neisseria* spp. infections	Terminal complement component deficiency
Escherichia coli bloodstream infection	Galactosemia
Deep *Candida* spp. infection	Myeloperoxidase deficiency
Disseminated *Mycobacterium* spp. infection	T-lymphocyte deficiency, IFNγ receptor deficiency, IL-12 defects
Pneumocystis jirovecii	T-lymphocyte deficiency
Recurrent/severe *Streptococcus pneumoniae* bloodstream	Asplenia, hemoglobinopathy, agammaglobulinemia, mannose-binding lectin deficiency, IRAK4 deficiency

infection	
Recurrent/severe *Staphylococcus aureus* infection	Chronic granulomatous disease, hyper-IgE/recurrent infection syndrome, Chédiak-Higashi syndrome, IRAK4 deficiency

IFNγ, interferon γ; IgE, immunoglobulin E; IL, interleukin; IRAK4, interleukin 1 receptor−associated kinase 4.

Family History

Specific questions regarding the parents' ethnic heritage, the likelihood of parental consanguinity, early childhood deaths in the two previous generations, and gender bias in medical problems should be asked. Survival and significant illnesses and hospitalizations in all family members within two previous generations, as well as occurrence of peculiar infections or certain syndromes (e.g., collagen vascular diseases and lymphoreticular malignancy), should be documented. Consanguinity or close ethnic heritage of the parents, occurrence of multiple early childhood deaths (particularly of male sex) in the family, serious infections in other family members, or presence of recognized syndromes in other family members (e.g., discoid lupus in heterozygous carriers for X-linked chronic granulomatous disease) heighten concern. Collagen vascular diseases in family members (associated with some complement deficiency states) and the presence of lymphoreticular malignancies (associated with a variety of immunodeficiency diseases) are noteworthy.[19]

Birth History

Both congenital anatomic malformations and primary immunodeficiency disorders can manifest within days to weeks of birth. History is sought about the mother's prenatal care, prenatal illnesses, and exposures as well as the infant's length of gestation and peripartum problems, delayed separation of the umbilical stump (leukocyte adhesion deficiency type I), requirement for blood transfusion (graft-versus-host disease), and need for ventilator support. Historical details of concern include lack of prenatal care, maternal drug use or multiple sexual partners (human immunodeficiency virus or other congenital infection), presence of congenital malformations, absence of a thymic shadow on a neonatal chest radiograph, perinatal blood transfusion, perinatal ventilator therapy (resulting in chronic lung disease), onset of infection in the first days of life, intracranial hemorrhage (resulting in dysfunction of hypothalamic temperature regulation), prenatal exposure to a teratogen, and the need for surgical removal of the umbilical stump. Separation of the umbilical stump normally occurs within 14 days, and failure to separate is associated with leukocyte adhesion deficiency type 1. Of note, assiduous umbilical cord care (aggressive application of triple dye and isopropyl alcohol to "keep the cord stump clean") can lead to its desiccation and resultant failure to separate in normal infants.

Social History

Because the frequency of infection in small children mirrors frequency of exposure, details are sought of the patient's contacts with other children (e.g., siblings, classmates, playmates in childcare, nursery school, playgroups) that increase the frequency of exposures. In addition, exposure to tobacco smoke or other environmental pollutants affects infection rates and symptomatology, particularly in association with underlying atopy.

Review of the patient's dietary habits should include estimates of caloric intake and whether raw egg ingestion occurs (excessive intake of avidin can lead to nutritional biotin deficiency). The length of time at the current residence, the type and duration of parental employment, and the child's daily activities or school performance can yield insights into the continuity of medical care. The effect that "recurrent infections" has had on the child and family gives a measure of their severity.

Review of Systems

The review of systems should focus on infection by organ systems involved. Skin, mouth, nasopharynx, lungs, and gastrointestinal tract are sites of constant contact with the microbially contaminated external environment and are common sites of infection. The liver, spleen, and lungs provide defenses against systemic spread of infection and as a result can become sites of infection. The occurrence of cutaneous abscesses and extent of scarring when wounds heal, rashes (e.g., discoid lupus), rhinitis, dermatitis (generalized or localized, particularly behind the ears and in the diaper area), and paronychia provide clues to underlying disorders and the integrity of skin defenses. Questions about sinusitis, seasonal allergies, allergic shiners, snoring, and sleep disturbance (i.e., upper airway obstruction) explore the possibility of an allergic diathesis. Gingivitis, periodontal disease, retained primary teeth, and aphthous stomatitis can be associated with specific primary immunodeficiency disorders. Focused questioning about pneumonia, diarrhea, perirectal or pararectal abscess, liver abscess, lymphadenitis, and bloodstream infections can reveal details sometimes missed in general review of systems.

Physical Examination

Points to be addressed by the physical examination are (1) the physical status of the patient, (2) the presence of physical findings that confirm points of history, and (3) previously unrecognized but significant physiologic or anatomic abnormalities. Specific considerations during the physical examination are shown in Box 101.3.

Box 101.3

Specific Considerations During the Physical Examination

Reconcile vital signs with historical details (e.g., normal pulse and respiratory rate despite significant lung disease infers physiologic compensation and, therefore, chronicity)

Assess general habitus, growth, and development (chronically ill versus robust; developmental delay; dysmorphism suggesting a genetic syndrome)

Seek markers for atopy, nasopharyngeal lymphoid hyperplasia, or both

Identify lymphoid tissue (absence of palpable or visible lymphoid tissue suggesting T-lymphocyte deficiency)

Examine for midline defects in the head, neck, spine, or sacrum; or the presence of glucose-containing rhinorrhea

Examine for scarring of tympanic membranes

Examine for gingivitis, ulcerations, tooth loss, or periodontal disease (typical of immunodeficiency)

Identify cutaneous stigmata:

- Petechiae (suggesting Wiskott-Aldrich syndrome)
- Skin or conjunctival telangiectases (ataxia-telangiectasia syndrome)
- Eczematoid rash (Wiskott-Aldrich syndrome, hyperimmunoglobulinemia E [hyper-IgE] syndrome)
- Seborrhea-like dermatitis localized behind the ears (chronic granulomatous disease)
- Generalized seborrhea-like dermatitis (Langerhans histiocytosis, graft-versus-host disease, or T-lymphocyte deficiency)
- Nose-tip dermatitis (chronic granulomatous disease)
- Alopecia (graft-versus-host disease)
- Ectodermal dysplasia (anhidrotic ectodermal dysplasia with immunodeficiency)
- Cutaneous scars, with thin/poor formation at site of previous surgery or with tissue loss at site of previous infection (leukocyte defects)

Seek markers for chronic lung disease (pulmonary osteoarthropathy)

Assess for acute or chronic sinus disease

Identify the size of the liver and spleen

Examine for pararectal inflammation, scarring from previous infections, or persistent inflammation

Examine exhaustively any anatomic site where infections repeatedly localize, assessing normalcy of local anatomy and physiology

Laboratory Findings and Diagnosis

If the history and physical findings are consistent with an anatomic cause of infection or the presence of an underlying condition, laboratory evaluation of the patient is directed at either defining the anatomic problem or diagnosing the underlying condition. If the history and physical findings do not point to a cause for recurrent, significant infections, a screening laboratory analysis provides a reasonable first evaluation (Table 101.5).

TABLE 101.5

Screening Laboratory Tests and Their Purposes in the Evaluation of Immunodeficiency Disorders

Test	Purposes
Complete blood count differential	Assess numbers and morphology of cellular blood elements: leukopenia, leukocytosis, anemia, neutropenia, lymphopenia, Howell-Jolly bodies, bizarre erythrocyte forms, leukocyte morphology, thrombocytopenia
Total lymphocyte, T-lymphocyte, and B-lymphocyte quantification	CD3 marker is used to estimate total lymphocyte number by flow cytometry; CD4 and CD8 markers are used to estimate T-lymphocyte subsets; B-lymphocyte numbers are estimated using surface Ig expression or CD19 or CD20 markers
Skin testing	Simple assessment of cell-mediated immunity (T-lymphocyte function)
Serum immunoglobulin quantification (IgA, IgG, IgM, IgE)	Assess for hypergammaglobulinemia, hypogammaglobulinemia, or agammaglobulinemia
IgG subclass determinations	Assess for specific subclass deficiency
Specific antibody determinations	Assess production of antibody in responses to tetanus or diphtheria toxoid immunization as well as boosting; assess quantitative

	isohemagglutinin levels
Assess for Underlying Conditions	**Test**
Cystic fibrosis	Sweat test
HIV	HIV serology (and PCR testing, depending on patient age)
Sickle cell disease, thalassemia	Hemoglobin electrophoresis
Multiple congenital and acquired anomalies/conditions	Assess chest radiograph for chronic lung disease, foreign body, presence of thymus, situs inversus, anatomic abnormality, or end-organ damage If anatomic definition is inadequate, consider chest computed tomography
Terminal complement component deficiency	Total hemolytic complement activity (CH50)[a]

[a] Test performance is altered easily and unpredictably by inappropriate specimen handling and/or poor laboratory technique.

CD, cluster designation (for antigens); CH50, 50% hemolyzing dose of complement; HIV, human immunodeficiency virus; Ig, immunoglobulin; PCR, polymerase chain reaction.

Further Assessment

After the history, physical examination, and a screening laboratory evaluation have been completed, either the diagnosis will be clear and a plan of action can be proposed, or a diagnosis will be lacking and the decision must be made as to whether further, more detailed evaluation is appropriate. This decision is based on an overall impression of the severity, end-organ effects, documentation, and pathogens of the child's recurrent infections, family history, and physical findings. In the absence of repeated, documented infections in a patient in whom physical findings, growth and development, and appetite and activity are normal and the screening laboratory examination are unrevealing, the likelihood of a predisposing condition or immunodeficiency is remote and the child is assessed as “normal but unlucky.” Prospective observation and documentation should be planned and reassurance given.

Problems may resolve spontaneously, or documentation of continuing problems may reveal their cause or lead to a need for specialized evaluation. If there are major incongruities between physical findings, historical details, and laboratory results, or when an unexplained lack of continuity in patient care is obvious, Munchausen syndrome or Munchausen syndrome by proxy should be considered.[20]

Specialized Testing

If anatomic problems or underlying conditions are suspected, appropriate testing and imaging are pursued. If immunodeficiency is suspected or is likely, specialized, targeted testing is planned. Because the range of specialized testing is broad, an all-inclusive testing approach is both labor and time intensive, extremely costly, and inappropriate in most circumstances. Focused testing should be performed in a stepwise fashion, pursuing abnormalities uncovered by history, physical examination, and screening laboratory tests (Table 101.6).

TABLE 101.6

Specific Testing Approaches for Immunodeficiency Disorders

Disorder	Possible Testing Approaches
Cytopenia	Bone marrow examination/histochemistry
	Cytokine, colony-stimulating factor levels
Antibody deficiency	In vitro antibody production (Ig isotypes and subclasses)
	Cytokine levels
	In vitro specific antibody production
	Bruton thymidine kinase gene
T-lymphocyte deficiency	Adenosine deaminase activity
	Nucleoside phosphorylase activity
	In vitro proliferation responses (mitogens and specific antigens)
	Cytokine, growth factor levels
	Skin biopsy, intestinal biopsy (graft-versus-host disease)
Phagocytic cell dysfunction	Bactericidal activity Respiratory burst activity (nitroblue tetrazolium reduction, superoxide, dihydrorhodamine 123 oxidation test, or H_2O_2 production) Chemotaxis
Complement deficiency	CH50 Individual complement component quantitation Serum opsonic activity

CH50, 50% hemolyzing dose of complement; Ig, immunoglobulin.

Genetic Testing

Genetic testing is a powerful diagnostic tool in primary immunodeficiency disorders. Current information on characteristics and genetics of most disorders is available at the OMIM website (www.omim.org). The genes responsible for all of the known X-linked and most of the known autosomal primary immunodeficiency disorders have been elucidated. For the X-linked disorders, approximately one third of new cases are due to new mutations, and two thirds are inherited.[21] Carriers of some X-linked conditions (e.g., X-linked severe combined immunodeficiency, X-linked agammaglobulinemia, Wiskott-Aldrich syndrome) sometimes can be identified through the use of X-chromosome inactivation analysis because cells expressing the normal X chromosome have a survival advantage over cells expressing the abnormal X chromosome.[22–25] Carriers are recognized because of their homogeneous X-chromosome expression pattern (except in situations of "extreme" lyonization). In classical autosomal recessive conditions, recurrence risks follow mendelian inheritance.

Well over 100 genes have now been associated with primary immunodeficiency diseases.[9] Although the availability of appropriate gene probes or diagnostic methods for most currently recognized primary immunodeficiency syndromes makes their diagnosis easier than in the past, clinical suspicion remains the fulcrum for testing. In some instances, the suspicion only arises after the death of an index patient; if specimens of tissues are appropriately preserved, genetic testing can be performed postmortem.

Management

When a child is identified with an anatomic abnormality, an underlying condition, or a primary immunodeficiency disorder, management is based on existing knowledge about the specific condition, as described in subsequent chapters. Management is more difficult for patients whose history or physical findings are suggestive of a defect but in whom diagnostic testing is unrevealing. Such patients often require management based more on skilled judgment and careful reassessment than on scientific knowledge. It is important to emphasize to parents that, although negative diagnostic test results cannot exclude all potential underlying conditions, they eliminate specific serious conditions; this information can be comforting and helpful. In addition, delineating a specific plan for ongoing observation communicates a commitment to the child's well-being, which will help to ensure adherence to medically recommended interventions and continued contact with the patient.

Infectious Complications of Antibody Deficiency

Elisabeth E. Adderson

Antibodies play a central role in protective immunity against bacterial and certain viral infections. Immunoglobulin (Ig) molecules consist of two identical light chains and two identical heavy chains held together by disulfide bonds. There are two types of light chains (κ and λ) and five classes, or isotypes, of heavy chains (IgG, IgA, IgM, IgD, and IgE). There also are subclasses of IgG (IgG_1, IgG_2, IgG_3, and IgG_4) and of IgA (IgA_1 and IgA_2). The antigen-binding amino-terminal variable regions of Ig molecules are unique for each B-lymphocyte clone. The carboxyl-terminal constant regions are the same for each isotype or subclass.

Antibodies bind to specific antigens through the variable region of the Ig molecule. The constant region then performs an effector function, such as activation of complement, binding to a phagocytic cell, or antibody-dependent cell-mediated cytotoxicity. In some circumstances, the antigen-specific binding region functions alone by blocking the binding of a toxin or an infectious agent to the surface of a target cell. Different antibody isotypes are more or less efficient at providing different effector functions.

B lymphocytes develop from a pluripotent precursor stem cell to IgM-expressing immature cells in the bone marrow, a process that does not require contact with antigen (Fig. 102.1). Further differentiation to mature B lymphocyte and to memory B or plasma cells takes place in peripheral lymphoid organs beginning about a week after antigen stimulation. Activated B lymphocytes can undergo a change in isotype expression from IgM to IgG, IgA, or IgE. Genes encoding variable regions also can undergo somatic hypermutation, a process that increases the affinity of antigen binding by antibody. Re-exposure to an antigen results in an accelerated memory (or secondary) immunologic response—this is responsible for the more rapid and greater magnitude of Ig responses to "booster" vaccinations compared with primary antigen exposures.

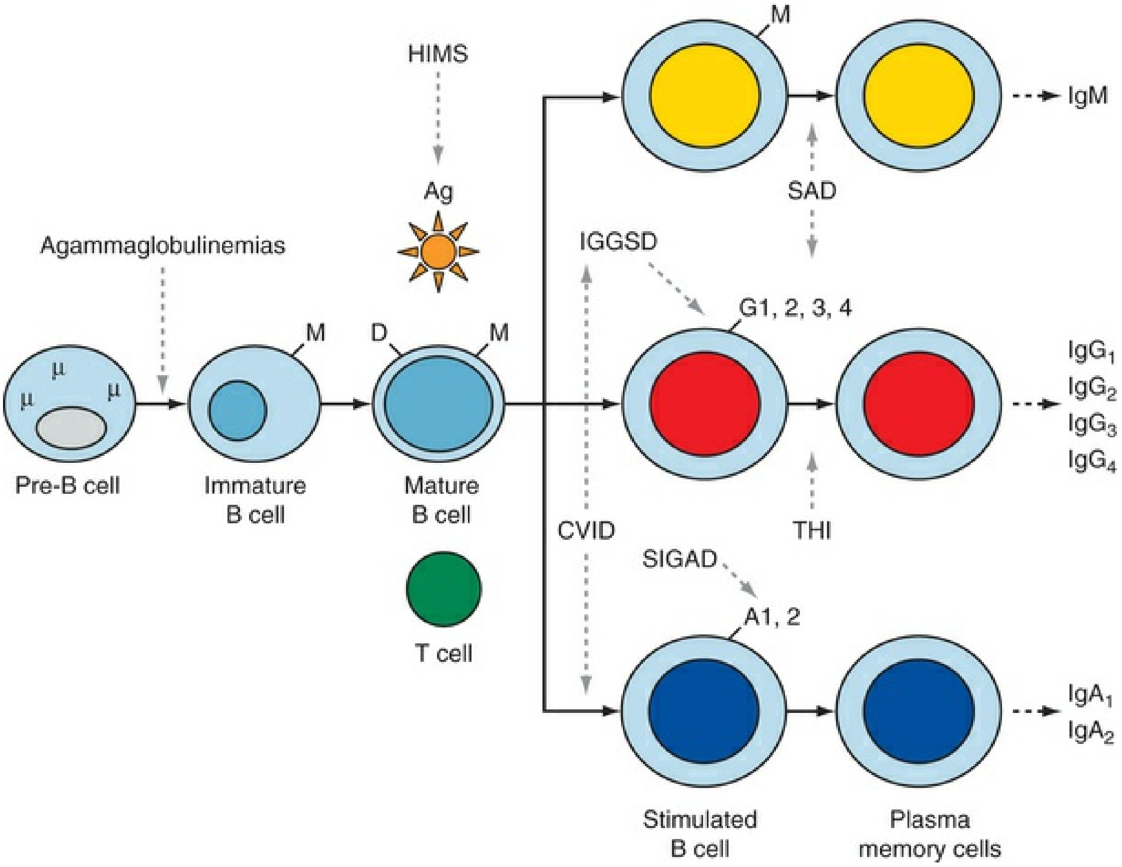

FIGURE 102.1 Normal antibody synthesis and primary deficiencies. μ, heavy chain of immunoglobulin (Ig) M; A, IgA; Ag, antigen; CVID, common variable immunodeficiency; D, IgD; G, IgG; M, IgM; HIMS, hyper-IgM syndromes; IgGSD, IgG subclass deficiency; SAD, specific antibody deficiency; SIgAD, selective IgA deficiency; THI, transient hypogammaglobulinemia of infancy.

Primary humoral immunodeficiencies have a prevalence of 13.9 to 18.1 per 100,000 persons in the United States.[1] The classification of these disorders was updated in 2014 by the International Union of Immunological Societies (Table 102.1), and diagnostic criteria for some have been published.[2,3] Antibody-mediated or humoral immunity is particularly important in the defense against infection caused by polysaccharide-encapsulated bacteria such as *Streptococcus pneumoniae* and *Haemophilus influenzae,* as well as some viral (poliovirus, nonpolio enteroviruses) and protozoan *(Giardia lamblia)* pathogens. In some antibody deficiency disorders, immunodeficiency is present prenatally, but transplacental transfer of maternal IgG in pregnancy protects infants against infection in the first several months of life. Children with severe antibody deficiency typically become symptomatic after this passively transferred immunity wanes. The onset of other humoral immunodeficiencies can be delayed until adolescence or adulthood, and some may be progressive. Among children, the average prevalence of humoral immunodeficiencies is highest in those aged 1 to 5 years (29–67 per 100,000).[1]

TABLE 102.1

Immunodeficiencies Predominantly Involving Antibody Deficiency

Category	Immunologic Features	Genetic Defects	Clinical Features
Agammaglobulinemias	All Ig isotypes severely reduced Absent (<2%) B lymphocytes Absent specific antibody responses	X-linked agammaglobulinemia (mutations in *BTK*) AR agammaglobulinemia [mutations in μ heavy chain, λ5, *Iga* (*CD79a*), *Igb* (*CD79b*), *BLNK*, *PIK3R1*] AD agammaglobulinemia (mutations in *TCF3*)	Recurrent and severe bacterial infections Chronic diarrhea Chronic enteroviral infections
Common variable immunodeficiency-like disorders	IgG low, IgA normal or low, IgM normal or low Normal or low numbers of B lymphocytes Poor specific antibody responses	Common variable immunodeficiency (unknown mutation) AR inheritance [mutations in *ICOS*, *CD19*, *CD81*, *CD20*, *CD21*, *TACI*, *LRBA*, *BAFF-R* (*TNFRSF13C*)] AD inheritance (mutations in *TWEAK*, *NFKB2*, *TACI*) WHIM (warts, hypogammaglobulinemia,	Recurrent infections Allergic disease Autoimmune disorders Malignancy

		infections, myelokathexis) syndrome (AD inheritance, mutations in *CXCR4*)	
Class switch recombination defects (hyperimmunoglobulin M syndromes)	IgG and IgA low, IgM normal or elevated Normal numbers of B lymphocytes Absent or poor specific antibody responses	X-linked inheritance (mutations in *CD40LG*) AR inheritance (mutations in *CD40*, *AICDA*, *UNG*)	Recurrent infections Opportunistic infections Lymphoid hyperplasia Autoimmune disorders
Isotype or light chain deficiencies with generally normal numbers of B lymphocytes			
Isotype deficiency	At least 1 IgG, IgA isotype and/or IgE absent Normal specific antibody responses	AR inheritance (mutations in 14q32 of chromosome 14)	Most asymptomatic
Kappa light chain deficiency	Kappa light chains absent Normal specific antibody responses	AR inheritance (mutations in *Cκ*)	Asymptomatic
IgG subclass deficiency	Normal total IgG and IgM At least 1 IgG subclass low Variable specific antibody responses	Unknown mutation	Most asymptomatic Recurrent sinopulmonary infections Allergic disease Autoimmune disorders
Selective IgA deficiency	IgG and IgM normal, IgA low; secretory IgA usually absent Specific antibody responses usually normal	Unknown mutation	Most asymptomatic Recurrent sinopulmonary infections Allergic disease Autoimmune disorders Anaphylactic reaction to IgA containing blood products
IgA deficiency with IgG subclass deficiency	Total IgG and IgM normal, IgA low, at least 1 IgG subclasses low	Unknown mutation	Recurrent sinopulmonary infections Allergic disease Autoimmune

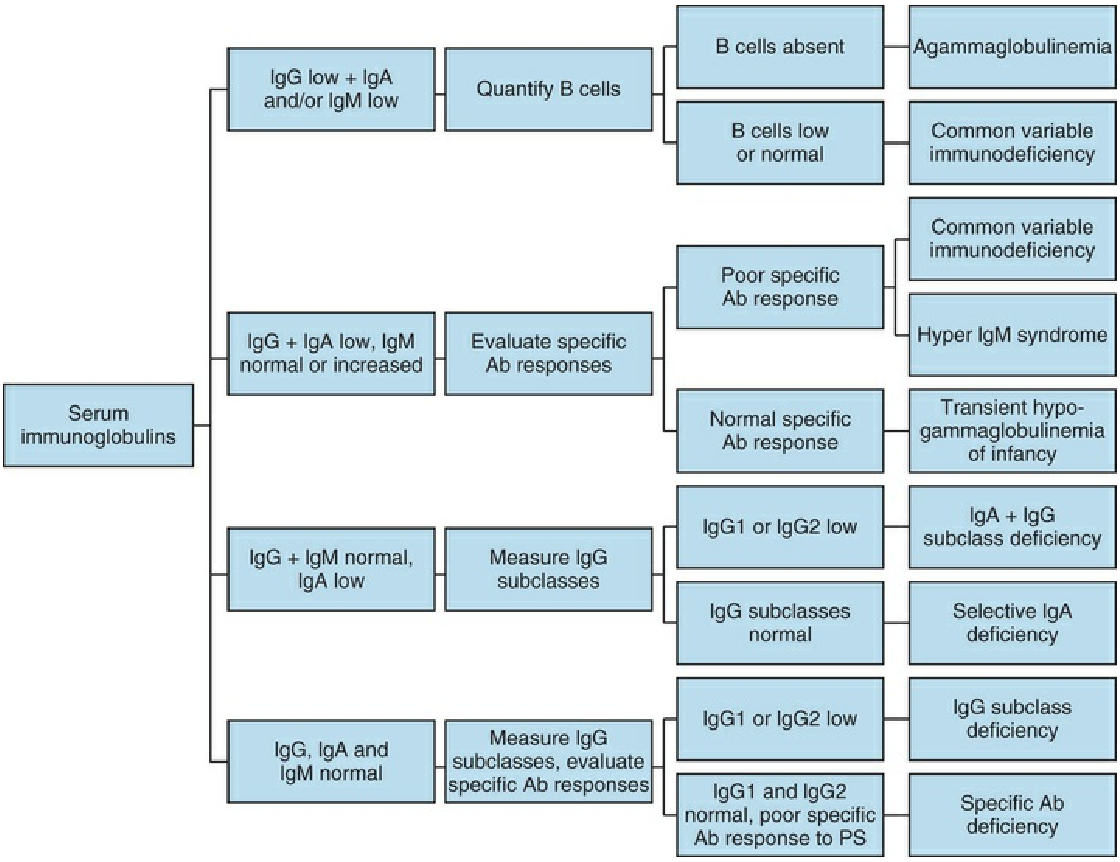
	Specific antibody responses usually normal		disorders Anaphylactic reaction to IgA containing blood products
Activated phosphatidylinositol-3-OH kinase-delta (PI3K-∂) syndrome (immunodeficiency 14)	IgG and IgA low, IgM normal or elevated Decreased numbers of T and B memory lymphocytes Absent or poor specific antibody responses	AD inheritance (mutation in *PIK3CD*)	Recurrent sinopulmonary infections beginning in childhood Chronic viral infection Lymphoproliferation Epstein-Barr virus associated lymphoma
Protein kinase C delta (PRKC∂) deficiency	IgG low, IgA and IgM elevated Progressive decrease in numbers of B lymphocytes	AR inheritance (mutations in *PRKCD*)	Recurrent infection Autoimmune disorders Autoimmune lymphoproliferative syndrome
Specific antibody deficiency	Normal IgG, IgA and IgM Normal numbers of B lymphocytes Poor IgG response to polysaccharide antigens	Unknown	Recurrent sinopulmonary infections Allergic disease
Transient hypogammaglobulinemia of infancy	Low IgG, variable IgA and IgM Normal numbers of B lymphocytes Specific antibody responses usually normal	Unknown	Recurrent infections

AD, autosomal dominant; AR, autosomal recessive.

Approach to the Patient With Suspected Antibody Deficiency

A primary antibody deficiency should be considered in children with recurrent or chronic sinopulmonary infections, particularly in association with (1) poor growth, (2) unusual or unusually severe infections, (3) chronic or recurrent diarrhea, (4) a family history of recurrent and severe infections or of early childhood deaths, or (5) granulomatous or autoimmune disease.[4] Physical features suggesting humoral immunodeficiency include absent or small lymph nodes and tonsils, chronic lymphadenopathy, a dermatomyositis-like rash, and hypertrophic osteoarthropathy.[5,6]

Timely diagnosis of primary antibody deficiency and institution of immunoglobulin replacement therapy reduces the morbidity and mortality associated with these disorders. Quantitative serum immunoglobulin concentrations should be compared with normal values for age, and reduced levels of IgG, IgM, or IgA (or normal levels in the presence of a clinical picture strongly suggestive of antibody deficiency) should prompt additional investigations (Fig. 102.2). B lymphocytes (CD19$^+$) are quantified by flow cytometry. The ability to generate a specific antibody response is assessed by measuring serum isohemagglutinins (naturally occurring antibodies to ABO blood group antigens) and antigen-specific serum antibody concentrations before and after vaccination with protein (e.g., tetanus, diphtheria, pertussis) and polysaccharide antigens (e.g., pneumococcal polysaccharide vaccine in children older than 2 years). Quantifying IgG subclasses may be helpful in some cases, but the wide range of normal values and an inconsistent correlation between low serum concentrations and clinical disease complicate the interpretation of results, particularly in younger children. Evidence of the decreased expression or function of a specific gene product may be useful, but these tests generally are available on a research basis only. A definitive diagnosis is possible for disorders caused by known genetic mutations. Carrier detection and prenatal diagnosis also are possible in some cases.



Serum immunoglobulins
IgG low + IgA and/or IgM low
Quantify B cells
B cells absent
Agammaglobulinemia
B cells low or normal
Common variable immunodeficiency
IgG + IgA low, IgM normal or increased
Evaluate specific Ab responses
Poor specific Ab response
Common variable immunodeficiency
Hyper IgM syndrome
Normal specific Ab response
Transient hypo-gammaglobulinemia of infancy
IgG + IgM normal, IgA low
Measure IgG subclasses
IgG1 or IgG2 low
IgA + IgG subclass deficiency
IgG subclasses normal
Selective IgA deficiency
IgG, IgA and IgM normal
Measure IgG subclasses, evaluate specific Ab responses
IgG1 or IgG2 low
IgG subclass deficiency
IgG1 and IgG2 normal, poor specific Ab response to PS
Specific Ab deficiency

FIGURE 102.2 Algorithm for the evaluation of common primary antibody deficiency disorders. Ab, antibody; PS, polysaccharide.

Patients with primary antibody deficiencies and severe symptoms should receive immunoglobulin replacement therapy, which reduces the rate and severity of infections. Ideally, trough serum IgG concentrations (immediately before the next administration of immunoglobulin) should be within the normal range of healthy persons. Increasing use has been made of rapid subcutaneous infusion and home or infusion center programs.[7] Immunoglobulin replacement therapy does not prevent all infections, however, and signs and symptoms of infection should be evaluated promptly and breakthrough infections treated aggressively. Some patients, particularly those with frequent or chronic respiratory infections, may benefit from prophylactic antibacterial therapy. Patients with hyperimmunoglobulin M syndrome (HIMS) caused by CD40L or CD40 deficiency have an increased susceptibility to *Pneumocystis jirovecii* infection and should receive trimethoprim-sulfamethoxazole or other effective prophylaxis. Vaccines composed of live, attenuated virus should not be administered to patients known or suspected of having a clinically significant primary antibody deficiency, with the exception of persons with selective IgA deficiency.

Infectious Complications of Antibody Deficiency Syndrome

Severely Reduced IgG, IgA, and IgM Levels With Absent B Lymphocytes (Agammaglobulinemia)

The prototype of antibody deficiency syndromes is X-linked agammaglobulinemia (XLA), which has an incidence of approximately 1 in 200,000 persons and accounts for about 85% of cases of agammaglobulinemia (Box 102.1).[2–5] XLA is caused by mutations in the Bruton tyrosine kinase gene, *BTK,* which is required for the normal differentiation of pro–B lymphocytes to pre–B lymphocytes and mature B lymphocytes.[8,9] A family history of male relatives with recurrent infections is common, but about one half of patients represent new mutations. The severity of infectious complications can differ among family members with the same mutation. Prenatal diagnosis and carrier detection are possible if the mutation is known. Rare autosomal recessive agammaglobulinemias result from mutations in other genes important to B-lymphocyte development, including μ heavy chain, *λ5*, *Igα* (*CD79a*), *Igb* (*CD79b*), B-cell linker (*BLNK*), phosphoinositide 3-kinase (*PIK3R1*), and transcription factor 3 (E47 transcription factor).[2–5,10–16]

Box 102.1

Agammaglobulinemia

Clinical Presentation

- Onset in infancy or early childhood
- Recurrent respiratory and invasive infections, especially *Haemophilus influenzae* type b, *Streptococcus pneumoniae*
- Chronic diarrhea, malabsorption, chronic *Giardia* and rotavirus infection

- Chronic enteroviral meningoencephalitis, poliomyelitis, dermatomyositis-like syndrome
- Neutropenia with infection
- Lymph nodes and tonsils absent or small

Diagnosis

- IgG, IgM, and IgA >2 standard deviations below mean for age
- Peripheral blood $CD19^+$ B lymphocytes <2%
- Poor specific antibody responses, including isohemagglutinins
- Genetic testing

Treatment

- Immunoglobulin replacement

Serum IgG, IgA, and IgM levels are very low (>2 standard deviations [SD] below the mean value for age), and patients have poor or no specific antibody responses after infection or immunization.[3] Circulating $CD19^+$ B lymphocytes are absent or present in very low proportions (generally <2%). Plasma cells are absent from lymph nodes and bone marrow, and lymph nodes and tonsils are absent or small. T lymphocytes are normal in both number and function. Neutropenia can occur in association with acute infections.[17]

Transplacentally acquired maternal IgG typically protects infants with agammaglobulinemia from infection in the first few months of life. Thereafter, affected children have recurrent bacterial infections, particularly otitis media, sinusitis, and pneumonia. More than one half of patients are symptomatic by 1 year of age, and almost all are by 5 years of age.[18] Invasive bacterial infections (septicemia, meningitis, osteoarticular infections) also are common. Encapsulated bacteria, particularly *H. influenzae* type b (Hib), *S. pneumoniae, Staphylococcus aureus,* and *Pseudomonas* spp. cause most infections. Up to 50% of patients experience chronic diarrhea, steatorrhea, or malabsorption. In some cases, these symptoms have been associated with chronic rotavirus and *Giardia lamblia* infections.[19,20] The incidence of enteritis due to *Salmonella* spp. and *Campylobacter jejuni* is higher in persons with agammaglobulinemia than in the general population. Persistent *Mycoplasma* and *Ureaplasma* infections of the respiratory tract, joints, and urogenital tract also occur.

Although children with antibody deficiencies usually manifest greater susceptibility to bacterial than to viral infections, some children with agammaglobulinemia have severe and chronic enteroviral infections. In regions of the world where wild-type poliovirus or live vaccine strain polioviruses circulate, paralytic disease in patients with agammaglobulinemia can occur.[21] Meningitis caused by nonpolio enteroviruses also can occur and either can have an insidious onset with ataxia, loss of cognitive skills, and paresthesias or present more acutely with fever, headache, and seizures. Central nervous system (CNS) enterovirus infection may be the initial manifestation of XLA and can occur despite immune globulin intravenous (IGIV) replacement therapy. Cerebrospinal fluid (CSF) pleocytosis with a lymphocytic predominance, increased protein levels, and decreased glucose levels are typical, although some children have normal or only mildly abnormal findings. CSF abnormalities tend to worsen with clinical exacerbations. Some individuals with chronic enteroviral infections develop a dermatomyositis-like syndrome characterized by muscle weakness, edema and woody induration of the skin, and a violaceous rash over the extensor surfaces of joints, often accompanied by hepatitis.[21]

The prognosis of XLA has improved greatly with IGIV therapy, particularly when therapy is initiated at an early age. Aggressive and prolonged treatment of bacterial infections is critical. Patients with chronic enteroviral meningoencephalitis are treated with high doses of IgG (to maintain trough levels of >1000 mg/dL) or with plasma or immune serum known to have high antibody titers to the enterovirus causing the infection.[21] Intrathecal IGIV also has been used. The most common causes of death among patients with agammaglobulinemia are chronic enteroviral and pulmonary infections.

Severely Reduced IgG, IgA, and /or IgM Levels With Normal or Low Numbers of B Lymphocytes (Common Variable Immunodeficiency Disorder)

Common variable immunodeficiency disorder (CVID) represents a heterogeneous group of disorders characterized by low serum Ig concentrations, defective production of specific antibodies, and an increased susceptibility to respiratory and gastrointestinal tract infections (Box 102.2).[2,3,22] CVID affects 1 in 25,000 to 1 in 50,000 persons and has an equal prevalence in males and females. Persons with CVID have serum total IgG concentration ≥2 SD below the mean for their age, a marked decrease in IgA, normal or low IgM, and impaired specific antibody responses.[3] Numbers of peripheral B lymphocytes can be normal, reduced, or increased. Current diagnostic criteria restrict CVID to children who are older than 4 years, in part owing to the need to exclude other immunodeficiencies that manifest earlier in life. CVID can develop in persons who initially present with clinical and laboratory findings suggestive of selective IgA or IgG subclass deficiencies. Immunodeficiency can be progressive.[22]

Box 102.2

Common Variable Immunodeficiency

Clinical Presentation

- Onset 2 years of age to adulthood
- Recurrent and severe sinopulmonary infections, especially *Streptococcus pneumoniae, Haemophilus influenzae*
- Gastrointestinal infections, especially *Giardia, Campylobacter jejuni, Salmonella* spp.
- Chronic *Mycoplasma* infection
- Severe infections due to hepatitis C, cytomegalovirus, varicella-zoster virus, enteroviruses
- Autoimmune and inflammatory disorders (gastrointestinal

lymphoid hyperplasia, inflammatory bowel disease, autoimmune cytopenias, arthritis, vasculitis)

- Lymphoid hyperplasia, splenomegaly, peripheral lymphadenopathy
- Increased risk for lymphoma, gastric carcinoma

Diagnosis

- IgG usually >2 standard deviations below mean for age; young children may present with progressive IgG subclass deficiency
- IgA usually >2 standard deviations below mean for age
- IgM normal or low
- Peripheral blood CD19$^+$ B lymphocytes normal or reduced
- Poor specific antibody responses, absent isohemagglutinins
- Genetic testing available for some forms

Treatment

- Immunoglobulin replacement

The genetic basis of most CVIDs is not known. Approximately 25% of cases are familial.[23] Most have autosomal recessive inheritance and result from mutations in B-lymphocyte surface receptors, transmembrane proteins involved in B-lymphocyte signaling pathways, or costimulatory molecules expressed on T lymphocytes.[24–27] Other immunodeficiencies, including the agammaglobulinemias, class switch recombination defects, X-linked lymphoproliferative disease, and "leaky" severe combined immunodeficiency syndromes can resemble CVID. Warts, hypogammaglobulinemia, infections, and myelokathexis, also known as *WHIM syndrome*, represent an autosomal dominantly inherited disorder characterized by hypogammaglobulinemia, recurrent sinopulmonary and invasive bacterial infections, peripheral neutropenia with bone marrow hypercellularity, a distinctive neutrophil morphology, and increased susceptibility to human papillomavirus infection.[28] Certain drugs, chromosomal abnormalities, infection, malignancy, and systemic illnesses are associated with secondary CVID.

Symptoms of CVID are unusual in children younger than 2 years. Bimodal peaks of incidence are recognized at 2 to 5 and 16 to 28 years of age.[29] Patients most commonly have recurrent sinopulmonary infections, chiefly due to bacteria such as *S. pneumoniae, H. influenzae, Moraxella catarrhalis,* and *Mycoplasma pneumoniae.* Recurrent pneumonia sometimes progresses to bronchiectasis. Invasive bacterial infections occur in 10% to 25%. Enteric infections caused by *Giardia* spp., *C. jejuni,* and *Salmonella* spp. are frequent and can be more severe and prolonged than in immunocompetent persons. Chronic genitourinary tract, joint, and systemic infections caused by *Mycoplasma* spp. have been described. Although most viral infections are not complicated in patients with CVID, an increased frequency and severity of hepatitis C virus, cytomegalovirus (CMV), measles, and varicella-zoster virus infection has been reported.[22,29] Complications of enteroviral infection, including chronic encephalomyelitis and dermatomyositis-like syndrome, occur but are less frequent than with the agammaglobulinemias.[4]

Allergic disorders are found in more than 30% of children and adolescents with CVID.[30] Inflammatory or autoimmune diseases occur in 20% to 35% of patients and can cause more serious morbidity than infections. Granulomatous pulmonary disease, lymphocytic interstitial pneumonitis, and chronic lymphadenopathy have been reported. Inflammatory bowel disease, lymphonodular hyperplasia, or malabsorption affect up to 25% of patients, and hematologic disorders such as autoimmune thrombocytopenia, hemolytic anemia, neutropenia, and pernicious anemia occur in 10%. About one fourth of patients have significant growth restriction.[30] The incidence of some cancers, particularly lymphomas and gastric carcinoma, is markedly elevated in patients with CVID, occurring predominantly in adults.

Most patients with CVID require Ig replacement therapy. Prophylactic antibiotics may benefit some patients, particularly those with recurrent respiratory infections and bronchiectasis. Patients require careful monitoring for autoimmune and lymphoproliferative complications.

Reduced IgG and IgA With Normal or Elevated IgM and Normal Numbers of B Lymphocytes (Class Switch Recombination Defects, Hyperimmunoglobulin M Syndrome)

Children with HIMS have recurrent or serious infections in the first 5 years of life, absent or low levels of serum IgG, normal or elevated serum IgM, absent or poor specific immune responses, normal or elevated numbers of B lymphocytes, and normal numbers of T lymphocytes (Box 102.3).[3,5,31]

Box 102.3

Class Switch Recombination Disorders (Hyper-IgM Syndromes)

Clinical Presentation

- Onset in infancy or early childhood
- Recurrent and severe sinopulmonary infections
- *Pneumocystis jirovecii* infection
- Severe or chronic *Cryptosporidium* and *Giardia* infections
- Neutropenia, parvovirus-induced aplastic anemia
- Autoimmune and lymphoproliferative disorders (sclerosing cholangitis, diabetes, arthritis, inflammatory bowel disease, uveitis)

Diagnosis

- Serum IgG >2 standard deviations below mean for age
- Normal or elevated numbers of B lymphocytes
- Normal numbers of T lymphocytes

- Absent specific IgG immune response; normal isohemagglutinins
- Genetic testing

Treatment

- Immunoglobulin replacement
- *P. jirovecii* prophylaxis for patients with CD40L or CD40 deficiency
- Granulocyte colony-stimulating factor for chronic neutropenia
- Hematopoietic stem cell transplantation

HIMS is rare, affecting about 1 in 300,000 persons. Approximately 65% of cases are inherited in an X-linked recessive fashion and are due to mutations of the gene encoding CD40L *(TNFSF5)*.[32,33] Rare mutations of CD40 *(TNFRSF5)* cause a similar disorder with autosomal recessive inheritance.[34] B-lymphocyte signaling through CD40, which is required for isotype switching and the affinity maturation of antibody responses, is impaired in these disorders. Other cases of autosomal recessively inherited HIMS result from mutations of the activation-induced cytidine deaminase gene, *AICDA*, or activation-induced cytidine deaminase, *UNG*, the products of which are required for isotype switching from IgM to IgG and IgA.[2]

Patients with HIMS have serum total IgG concentration >2 SD below the mean for their age and impaired specific IgG responses, but most patients have normal isohemagglutinins, which are of the IgM isotype. Serum IgM levels are normal or increased. Circulating T- and B-lymphocyte numbers are within the normal range, but T-lymphocyte proliferation is impaired in patients with CD40L and CD40 deficiency.

Patients with CD40L and CD40 deficiency typically come to attention at 1 to 2 years of age.[35,36] Patients with CD40L/CD40 deficiency, who have impaired humoral and cellular immune responses, generally are more ill than patients with other antibody deficiency disorders. Most have recurrent or severe bacterial infections, especially affecting the respiratory and gastrointestinal tracts. A predisposition to *P. jirovecii* pneumonia, which is reported in 40% of patients, and to disseminated infections caused by *Cryptococcus* spp. CMV and herpes simplex virus infections distinguishes these disorders from other antibody deficiency disorders. More than one half of affected patients have diarrhea, commonly associated with *Cryptosporidium, Salmonella,* or *Giardia* spp., and poor growth. Sclerosing cholangitis, sometimes progressing to cirrhosis, is common and can be idiopathic or a complication of *Cryptosporidium* infection. Patients have a significantly increased risk for gastrointestinal and hepatic malignancies. Neutropenia and anemia occur in 25% to 65% of patients; neutropenia can be chronic or cyclic. Chronic anemia and pancytopenia also occur in association with human parvovirus B19 infection.

Patients with *AICDA* and *UNG* deficiency may be diagnosed only in adolescence or adulthood. Opportunistic infections are uncommon, but lymphoid hyperplasia, especially of cervical lymph nodes and tonsils, is more common than in CD40L/CD40 deficiency. Autoimmune and inflammatory complications, including neutropenia, diabetes, arthritis, hepatitis, and inflammatory bowel disease, are identified in approximately 20% of patients, including young children. Unlike CD40L/CD40 deficiency, patients with AICDA or UNG deficiency do not have an increased risk for malignancy.

IgG replacement therapy is the mainstay for therapy of the class switch recombination defect disorders. Patients with CD40L and CD40 deficiency should receive trimethoprim-sulfamethoxazole or other effective prophylaxis to prevent *P. jirovecii* infection. Patients should be counseled in regard to measures to prevent *Cryptosporidium* infections. Granulocyte colony-stimulating factor may be helpful to manage chronic neutropenia. Hematopoietic stem cell transplantation may be curative; younger patients and those without liver disease appear to have the best outcomes.[31] Carrier detection and prenatal diagnosis are possible if the specific mutation is known.

Isotype or Light Chain Deficiencies With Normal Numbers of B Lymphocytes

Ig Heavy Chain Deficiency.

Rarely, deletions in the heavy chain constant region genes affect the expression of one or more Ig isotypes. Decreased serum concentrations of one or more IgG or IgA isotypes, or both, with or without IgE deficiency, are the most common abnormalities. Most affected people do not have significant problems with recurrent or severe infections.

Kappa Light Chain Deficiency.

Individuals with partial or complete deficiencies of serum antibody containing kappa light chain have been described rarely.[37] Most have symptoms; lambda light chains appear to compensate for the absence of kappa light chains.

Isolated IgG Subclass Deficiency.

IgG subclass deficiency is defined as ≥1 serum IgG subclass levels >2 SD below the mean for the individual's age but with normal total serum IgG and IgM levels (Box 102.4).[2] Several biologic and technical problems complicate the study of selective IgG subclass deficiencies in children, including the wide range of normal values for each of the subclasses and marked differences among the subclasses in the length of time required to mature to adult serum levels. Some cases of absolute IgG subclass deficiency result from mutations in genes encoding the IgG constant regions, but the etiology of most defects is unknown.[38]

Box 102.4

IgG Subclass Deficiency and IgA Deficiency With IgG Subclass Deficiency

Clinical Presentation

- Age of onset variable
- Most are asymptomatic
- Recurrent sinopulmonary infections, bacteremia (*Haemophilus influenzae* type b, *Streptococcus pneumoniae*) more common in patients with IgA plus IgG subclass deficiency than those with isolated IgG subclass deficiency

Diagnosis

- ≥1 IgG subclass >2 standard deviations below mean for age
- Total IgG and IgM normal, IgA normal or low
- Normal numbers of B lymphocytes
- Antibody responses usually normal, impaired antipolysaccharide antibody responses in some patients with IgG_2 deficiency; normal isohemagglutinins

Treatment

- Immunoglobulin replacement in patients with recurrent or severe infections

Although some patients experience recurrent sinopulmonary infections or allergic or autoimmune disease, most patients with IgG subclass deficiencies are symptom free, and some deficiencies resolve over time.[39–41] The ability to make specific antibody is most relevant to symptoms and prognosis in Ig subclass deficiency, and evaluation should focus on this function. Patients should be managed according to their specific antibody responses and clinical status. Ig replacement therapy is reserved for patients with poor specific antibody responses and severe or recurrent infections.

Selective IgA Deficiency.

Selective IgA deficiency is defined as a serum IgA concentration of <0.07 g/L in the presence of normal total serum IgG and IgM levels. Usually, secretory IgA also is absent. Isolated IgA deficiency is the most common primary immunodeficiency, with an incidence ranging from 1 in 400 to 1 in 5000 persons. Children <5 years of age may have a physiologic delay in IgA expression, and some transient cases of IgA deficiency result from an exaggeration of this maturational delay.

The cause of most cases of selective IgA deficiency is unknown. Up to 20% are hereditary. IgA deficiency, CVID, and IgG subclass deficiency have been reported in the same family, suggesting that these conditions may be part of a spectrum of abnormalities caused by the failure of appropriate signaling for B-lymphocyte maturation.[42] Secondary IgA deficiency can result from the use of certain anti-inflammatory and anticonvulsant drugs.

Most patients with selective IgA deficiency have no related symptoms. One third have recurrent infections, particularly of the respiratory tract. People with selective IgA deficiency also have a higher incidence of allergy and autoimmune disorders than the general population.

As with IgG subclass deficiency, evaluation should focus on the patient's ability to generate specific antibody. Rarely, patients can benefit from Ig replacement therapy; however, minor amounts of IgA in IGIV preparations or other blood products may lead to the development of anti-IgA antibodies and result in severe anaphylactic reactions in IgA-deficient patients who receive such tranfusions.[43] Products low in IgA should be used if replacement therapy is necessary. In contrast to other primary antibody deficiency syndromes, routine vaccination with live, attenuated viral vaccines is not contraindicated in selective IgA deficiency.

Iga Deficiency With IgG Subclass Deficiency.

Persons with IgA deficiency who also have deficiencies in IgG subclasses or specific antibody production have a greater predisposition to infection than those with selective IgA deficiency alone (see Box 102.4). In addition to recurrent sinopulmonary infections, these patients have an increased risk for allergy, inflammatory gastrointestinal disease, and autoimmune disorders. Deficiency of IgG_2, in particular, is associated with recurrent otitis media and sinopulmonary infections in children.[44] The defects most commonly associated with IgA deficiency are deficiencies of IgG_4 (40%), IgG_2 (28%), and IgG_3 (17%). IgA, IgG_4, and IgG_2 deficiency sometimes coexist. Patients should be evaluated and managed in the same manner as those with selective IgA deficiency.

Protein Kinase C Delta (PRKCδ) Deficiency.

PRKCδ deficiency plays an important role in the negative regulation of B-lymphocyte proliferation and the development of immunologic tolerance.[45] A small number of patients with mutations in *PRKCδ* have been reported; these persons had recurrent infections, hypogammaglobulinemia, elevated IgA and IgM levels, progressive B-lymphocytic lymphopenia, and autoimmune disease or autoimmune lymphoproliferative syndrome–like disease.[46–48]

Activated Phosphatidylinositol-3-OH Kinase Delta (PI3Kδ) Syndrome (Immunodeficiency 14).

The p110δ subunit of phosphoinositide 3-kinase is selectively expressed in leukocytes and is critical for the differentiation of naïve T lymphocytes into memory precursor effector cells.[49] Patients with autosomal dominantly inherited gain-of-function mutations in *PI3Kδ* have been described who have recurrent sinopulmonary infections, class switch recombination defects (low IgG and IgA, elevated IgM), markedly diminished memory T and B lymphocytes, lymphoproliferative disorders, chronic Epstein-Barr virus or CMV viremia, Epstein-Barr virus–associated lymphomas, and autoimmune disease.[49–51]

Specific Antibody Deficiency With Normal IgG Concentrations and Normal B-Lymphocyte Numbers

Patients with specific antibody deficiency (SAD) have poor IgG responses to polysaccharide antigens such as pneumococcal and *H. influenzae* capsular polysaccharide (specific serum IgG <1.3 μg/mL, or less than a fourfold rise in specific antibody levels 1 month after vaccination) but have normal levels of serum Ig and IgG subclasses (Box 102.5). The incidence of SAD ranges from 0% to 10% in children with allergic disease and recurrent respiratory infections, but incidence in the general population is not known.[52,53] The defects responsible for SAD have not been identified; some cases are familial.

Box 102.5

Specific Antibody Deficiency

Clinical Presentation

- Age of onset variable

- Recurrent otitis media, sinopulmonary infections (*Haemophilus influenzae* type b, *Streptococcus pneumoniae*)
- Occasional invasive infections
- Allergic disease common

Diagnosis

- Normal serum total IgG, IgA, and IgM
- Normal numbers of B lymphocytes
- Poor response to vaccination with polysaccharide antigen (less than fourfold rise in serum specific IgG titer 4 weeks after vaccination or postvaccination serum-specific IgG <1.3 g/mL

Treatment

- Immunoglobuin replacement if severe or persistent infections

Children with SAD typically come to attention with recurrent sinopulmonary infections. Serious infections such as septicemia and meningitis can occur. Many children have associated allergic disease. The diagnosis of SAD in children is complicated by the physiologic delay in the development of specific immune responses to polysaccharide antigens and the poor standardization of laboratory testing for antipolysaccharide antibodies.[5,54] Responses of healthy children younger than 2 years to polysaccharide antigens generally are poor and may be unreliable until middle childhood. Serial testing often is required to conclude that a persistent deficiency exists. The natural history of the disorder is not well described. Although antibody responses generally improve with age, some patients progress to CVID. Most children who fail to respond to immunization with polysaccharide vaccines have adequate responses to polysaccharide-protein conjugate formulations. Rarely, children with SAD may benefit from a trial of Ig or prophylactic antibiotics if symptoms are severe and persistent.

Transient Hypogammaglobulinemia of Infancy

After birth, a healthy infant actively begins first making IgM, then IgG, and finally IgA. Simultaneously, passively transferred maternal IgG normally decreases with a half-life of 25 to 30 days, reaching a nadir between 3 and 6 months of age. Sometimes this physiologic trough in serum IgG concentrations persists beyond 6 months of age; this condition is called transient hypogammaglobulinemia of infancy (THI) (Box 102.6). The incidence of THI has been estimated to be 20 to 60 per 100,000 live births, and THI is slightly more common in males.[55] Children come to attention with recurrent respiratory or gastrointestinal tract infections. Rarely, patients experience invasive bacterial, fungal, or severe viral infections. Infants with THI have normal numbers of circulating B lymphocytes and generally have normal specific immune responses. Low serum concentrations of IgA are present in up to 80% of patients, and a smaller proportion of children have low serum IgM levels.

Box 102.6

Transient Hypogammaglobulinemia of Infancy

Clinical Presentation

- Onset 3 months to 3 years
- Recurrent sinopulmonary and respiratory viral infections
- Rarely invasive bacterial infections

Diagnosis

- IgG >2 standard deviations below mean for age
- IgM usually normal, IgA variable
- B-lymphocyte numbers usually normal
- Specific antibody responses usually normal, normal

isohemagglutinins

Treatment

- Most resolve by 2–4 years
- Immunoglobuin replacement if severe or persistent infections

The cause of the maturational delay in IgG production in THI is unknown. THI occurs with greater frequency in families with other immunodeficiency syndromes, but no specific genetic defects have been identified. THI is self-limited, with antibody concentrations typically normalizing by 2 to 4 years of age. The presence of invasive infections or poor specific antitetanus antibody responses at the time of presentation may identify children who will have more persistent immunodeficiency.[56] Most children with THI do not require specific treatment, but IGIV should be considered in children with frequent or severe infections. If initiated, the continued need for IGIV should be reassessed after 3 to 6 months.[5]

Complement in Control of Infectious Agents

Michael M. Frank

The collective term *complement* refers to a large group of plasma- and cell membrane–bound proteins that play a major role in first-line innate defense against a wide variety of infectious agents. The group contains at least 30 plasma- and cell membrane–bound proteins that function cooperatively in antimicrobial and inflammatory reactions.[1–5] A large number of additional proteins, perhaps 20 more, have been found to interact with selected proteins on the system. The complement proteins are evolutionarily old, and some were incorporated into the adaptive immune system as it developed to help promote a healthy immune response.[6,7] This chapter reviews the biochemistry and biology of complement and its role in host defense against infection, and illustrates infectious complications in individuals with inherited or acquired deficiencies of complement proteins; neither aspects are covered exhaustively. Hundreds of infectious agents are more pathogenic in the absence of complement-mediated host defense. Relatively few patients have complete complement protein deficiencies.[8,9] It has been thought that the system almost always functions normally and that defects generally are limited to a few clinical situations. Our understanding of complement has broadened in the past decade, and that definition of deficiency may have been too narrow.

Biochemistry and Biology of Complement

The basic biochemistry of the complement system was clarified decades ago.[10–12] Many biologically significant effects of the complement system are mediated by the third component of complement (C3) and the late acting proteins (C5, C6, C7, C8, and C9). However, C3 and C5 through C9 first must be activated by one of three effector pathways before generating biologic activities: the classical pathway, the alternative pathway, or the lectin pathway[11,12] (Fig. 103.1).

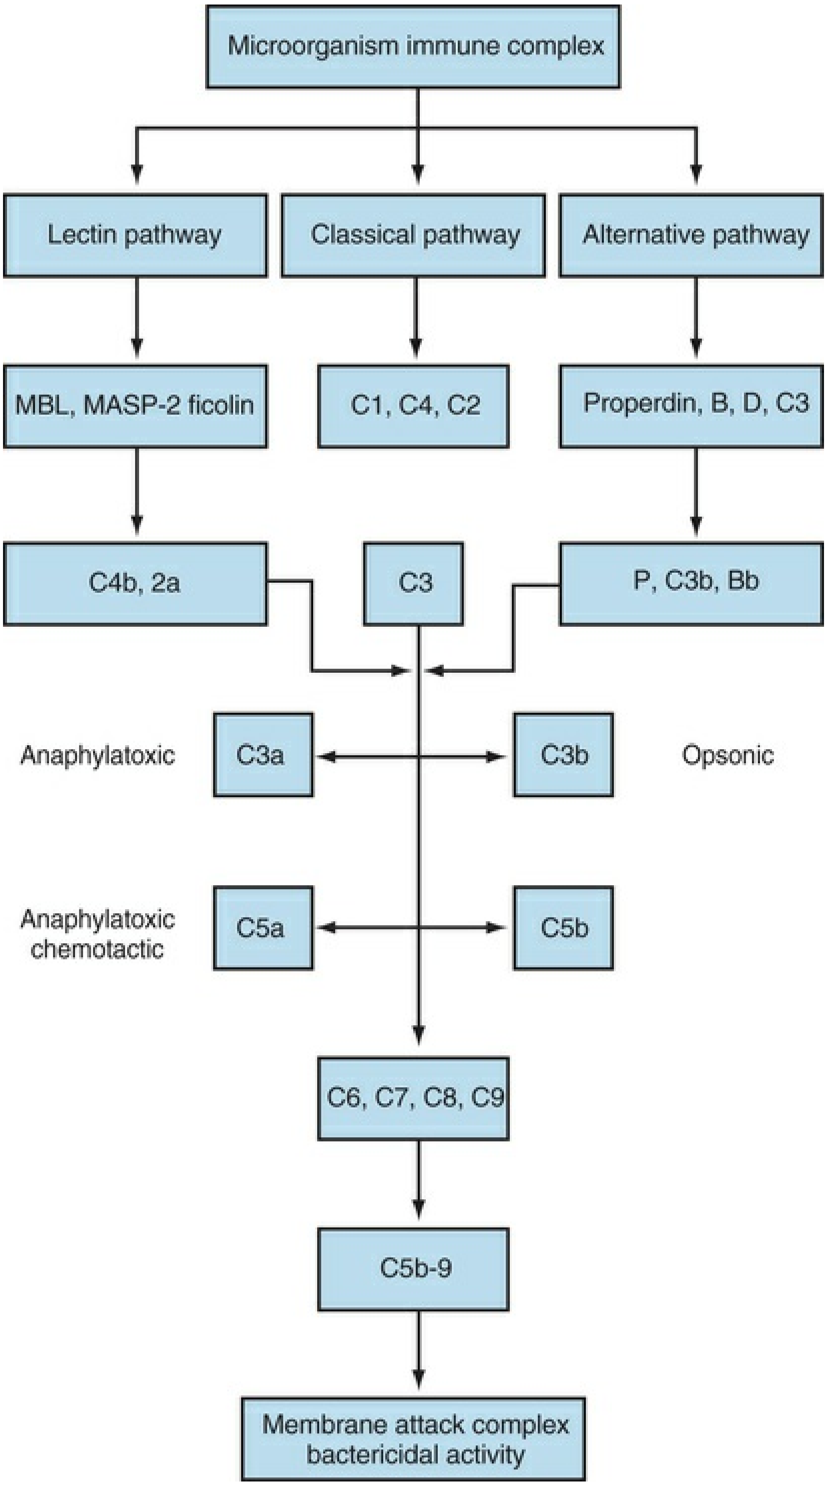

FIGURE 103.1 The complement system.

The Classical Pathway

The *classical pathway* is so termed because it was the first pathway of activation, studied more than 100 years ago.[10] In traditional experiments, complement activity was shown by the ability of the fluid phase complement proteins (components) to lyse antibody-sensitized erythrocytes. Activation of the classical pathway usually is initiated by antigen-antibody complexes. Antibodies of the appropriate class (immunoglobulin M [IgM] or IgG subclass IgG1, IgG2, IgG3) combine with microbial or other antigens to form an immune complex, which then binds and activates the first component of complement (C1). Only one molecule of pentameric IgM, deposited on a surface such as a cell membrane, is needed for activation of C1. In contrast, two IgG molecules, side by side, are necessary for C1 to bind and cause activation. The requirement for an IgG doublet greatly reduces the efficiency of IgG compared with IgM in activating C1 and the classical pathway because thousands of IgG molecules may need to be deposited on a microbial surface in order for two to be aligned in close proximity.[13]

C1 is a macromolecular complex composed of three biochemically distinct subcomponents, designated as C1q, C1r, and C1s. C1q binds to the Fc fragment of immunoglobulin molecules in the immune complex.[14] Binding is followed by cleavage of the bound C1r and then cleavage of C1s. Activated C1s then cleaves both the fourth component of complement (C4) and the second component (C2), each into smaller and larger products. The larger fragment of C2 (C2a) remains complexed with the larger fragment of C4 (C4b) to form a bimolecular enzyme, C4b2a, which is responsible for activating C3 and initiating the assembly of the terminal components.

Because the classical pathway usually is activated by antibody, it is considered to be important especially in "acquired" immunity. However, some enveloped RNA viruses, some *Mycoplasma* spp., and certain strains and species of both gram-negative and gram-positive bacteria bind C1q directly and activate the classical pathway.[5] Thus, under some circumstances, the classical pathway also can be activated in an antibody-independent fashion and functions in "natural" immunity.

Activation of C3

Because C3 function and structure play a critical role in the activation of the alternative pathway, C3 activation is considered before the alternative and lectin pathways.[15] C3 is a two-chain molecule with the chains designated α and β. One C3-activating enzyme (convertase) is formed by proteins of the classical and lectin pathways, as described. A second convertase is formed by the proteins of the alternative pathway. Hundreds of C3 molecules can be cleaved by each C3 convertase molecule, allowing for amplification of the response. C3 cleavage releases a small peptide (C3a) from the α chain into the fluid phase, where it acts as an anaphylatoxin.[16] C3a is a cell-activating molecule, and one of its actions is to induce histamine release from mast cells and basophils generating an anaphylaxis-like response. C3a also acts as an immune regulator, downregulating some immune responses.[16] The larger C3 fragment, C3b, binds to the activating complex. It is rapidly inactivated by hydrolysis, preventing its binding to targets. However, some C3b binds covalently to the microbial cell surface, where it acts as an opsonin.[15] The target-bound C3b can be degraded by circulating complement control proteins, factor H and factor I, the latter which interacts with C3b after binding to factor H, as well as by other proteases, yielding a variety of products.[17] However, if C3b is not degraded, it joins an alternative pathway C3 convertase to continue the complement cascade. C3b degradation is complex, and specific cellular membrane receptors recognize each of the degradation products; each appears to have a different biologic function. C3b itself is recognized by a specific receptor present on phagocytes and B lymphocytes, CD35 (sometimes termed *complement receptor 1* [CR1]). Binding of microbes to CD35 markedly enhances phagocytosis. The first step in C3b degradation leads to the decay fragment iC3b. This fragment with a cleaved α chain is recognized by the opsonization receptors CD11b/CD18 and CD11c/CD18 (two of the B2 integrins, also termed CR3 and CR4). These receptors are deficient or abnormal in leukocyte adhesion deficiency (LAD).[18] With this cleavage of the α chain, iC3b no longer supports the continued activation of the complement cascade. This fragment is further degraded in several steps to the final fragment C3d that is recognized by CD21 (CR2), a receptor present on B lymphocytes and follicular dendritic cells, which is important in antigen processing and immune response.

The Alternative Pathway

The alternative pathway provides an evolutionarily old and quite primitive innate immune defense mechanism.[15,18] Activation commonly begins with the C3 molecule itself. Native C3 contains an internal thiol ester in its α chain that, under normal physiologic conditions, undergoes continuous low-grade hydrolysis to create a "C3b-like" molecule, C3(H_2O). C3(H_2O) can bind a circulating alternative pathway protein, factor B, which allows factor B to be cleaved by a serine protease, factor D. Two cleavage products of factor B are generated: the larger Bb and smaller Ba. The association of the hydrolyzed C3 with Bb creates a new C3-cleaving enzyme, C3(H_2O)Bb (termed the *priming C3-convertase*), which is responsible for a continuous, low-grade cleavage of C3 and, hence, the generation of further nascent C3b. If nascent C3b binds covalently to a suitable surface, such as a bacterium, it can form a reversible complex with native factor B. This complex is cleaved by factor D to create a highly efficient C3-cleaving enzyme, C3bBb, termed the *amplification C3-convertase*. These convertases of the alternative pathway are not stable and, like the C3 convertase of the classical pathway, decay over time. Decay in the classical pathway is associated with release of C2, and in the alternative pathway it is associated with release of factor B of the convertase. Another circulating protein, properdin, stabilizes the alternative pathway convertase, and properdin binding to C3 appears also to act as an initiating factor of the alternative pathway.[19]

Antibody is not required for the activation of the alternative pathway; however, antibody enhances activation. Thus, the alternative pathway can participate in both innate and "acquired" antibody-mediated host defense.

Because C3b is both the product of the alternative pathway C3-cleaving enzyme and also forms part of it, the activation of C3 through the alternative pathway creates a positive-feedback amplification loop (see Fig. 103.1). Moreover, activation of the classical pathway, by creating nascent C3b, amplifies activation of the alternative pathway.

The Lectin Pathway

The lectin pathway is a third C3 activation pathway and, like the alternative pathway, is evolutionarily ancient.[20] Mannose-binding lectin (MBL) is a naturally occurring member of the collectin family of proteins and is capable of binding to a number of sugars on the surface of a variety of microorganisms, including human immunodeficiency virus (HIV), *Haemophilus influenzae, Neisseria meningitidis,* streptococci, and many others. In the circulation MBL is associated with three serine proteases: MBL-associated serine proteases 1 to 3 (MASP1, MASP2, and MASP3). The principal activation pathway involves MASP2, which, when activated, cleaves both C4 and C2 to create C4b2a with its C3 cleaving activity. Another less studied group of proteins of the lectin pathway, the ficolins, have similar structure and presumably similar function to MBL, but bind to acetylated sugars as targets.

Activation of Terminal Complement Components

After C3 convertases are formed and bind C3, leading ultimately to bound C3b, the convertase can then bind C5 and function as a C5 convertase. Activation of C5 by either the alternative or classical pathway by C5 convertases results in cleavage of the α chain of the C5 molecule to create a low-molecular-weight product, C5a, and a high-molecular-weight product, C5b, which remains bound to the activation site. The smaller cleavage product, C5a, is released into the fluid phase, where it, like C3a, acts as an anaphylatoxin.[21] In addition, C5a possesses potent chemotactic activity for neutrophils and monocytes and acts to activate a series of cells with C5a receptors (CD88). C5a facilitates phagocytosis by neutrophils and appears to play a role in the generation of FoxP3-positive induced regulatory T cells (iTregs). Nascent C5b combines with native C6 to initiate formation of the membrane attack complex, a multimolecular assembly of C5b, C6, C7, C8, and C9, which is capable of cytolytic and bactericidal activity.[22]

Control of Complement Activation

Uncontrolled complement activation can result in widespread immunopathologic damage to the host, and each step in the cascade is under complex control.[23] Each enzyme undergoes spontaneous decay under physiologic conditions. In addition, a number of control proteins inhibit the classical pathway (i.e., C1 esterase inhibitor, C4-binding protein, factor I, and decay-accelerating factor, CD55) and the alternative pathway (i.e., factors H and I and membrane cofactor protein, CD46).[17] The membrane attack complex, composed of C5b through C9, also is regulated by control proteins (i.e., CD59). Thus the activation of complement proceeds in a highly controlled process and is limited to the immediate vicinity of the initiating substance (e.g., a microbial surface). Infectious agents have evolved proteins that control or prevent complement activation or binding or specifically bind complement control proteins from serum, allowing them to evade host defense. Well-studied examples involve staphylococci,[24] gonococci,[25] and vaccinia virus.[26,27]

Role of Complement in Host Defense

The complement system is critical in the host's defense against infection caused by a wide variety of bacteria, viruses, and fungi.[27] Animals that are pharmacologically depleted of complement or genetically deficient in individual complement proteins are more susceptible to infection with *H. influenza*,[28] *S. pneumoniae*,[27,29] *Staphylococcus* spp.,[30] Sindbis virus,[31] influenza A virus,[27] meningococcus,[32] West Nile virus,[33] and *Candida* spp.[34] to name just a few.

The protective effects of complement appear to be most important in the first hours following the onset of infection, when complement helps to limit the spread of microorganisms from an initial focus of infection.[35] Complement also plays a critical role in the clearance of pathogens from the bloodstream.[5] Different proteins of the system participate in different aspects of host defense. For example, in vivo studies have shown that the chemotactic cell-activating activities associated with C5a are important in attracting neutrophils to the initial site of infection, whereas the opsonic activity of C3b is critical in the clearance of bacteria from the bloodstream.[5] After the invading organism has established an infection, complement activation can contribute to further tissue damage.

Genetically Determined Deficiencies

of Complement

Complete deficiency of a specific complement protein is relatively uncommon; only 78 patients throughout Europe were identified in a 2015 publication.[9] Most of the genetically determined deficiencies of the complement system are inherited as autosomal recessive traits.[36] However, C1 esterase inhibitor deficiency is inherited as an autosomal dominant trait, and properdin deficiency is inherited as an X-linked recessive trait (Table 103.1). Heterozygous individuals with one half the normal level of complement proteins usually do not have an increased incidence of infections, but susceptibility to infection is increased in many complete deficiencies. Many deficiencies are associated with rheumatic disorders and one, C1 esterase inhibitor deficiency, is associated with episodic attacks of angioedema.[37] A discussion of each protein deficiency is beyond the scope of this chapter, but each is reviewed in *Immune Deficiencies*, edited by Sullivan and Stiehm.[36]

TABLE 103.1

Genetically Determined Deficiencies of Complement Associated With an Increased Susceptibility to Infection

Deficiency	Chromosomal Location	Inheritance	Major Clinical Manifestations
C1q	1p	Autosomal recessive	Rheumatic disorders and pyogenic infections
C1r or C1s	12p	Autosomal recessive	Rheumatic disorders and pyogenic infections
C4	6p	Autosomal recessive	Rheumatic disorders and pyogenic infections
C2	6p	Autosomal recessive	Rheumatic disorders and pyogenic infections
C3	19p	Autosomal recessive	Pyogenic infections and rheumatic disorders
C5	9q	Autosomal recessive	Meningococcal septicemia and meningitis
C6	5q	Autosomal recessive	Meningococcal septicemia and meningitis
C7	5q	Autosomal recessive	Meningococcal septicemia and meningitis
C8	1p(a,b)	Autosomal recessive	Meningococcal septicemia and meningitis
	9q(γ)	Autosomal recessive	Meningococcal septicemia and meningitis
C9	5p	Autosomal recessive	Meningococcal septicemia and meningitis
Factor I	4q	Autosomal	Pyogenic infections

		recessive	
Factor D	19p	Autosomal recessive	Systemic meningococcal infections
Properdin	Xp	X-linked recessive	Meningococcal septicemia and meningitis
Mannose binding lectin	10q11	Autosomal dominant	Infection and increased rheumatic disease

Patients with inherited total deficiency of complement proteins develop certain types of infection depending on the function of the deficient protein in host defense. Patients with a deficiency in C3-dependent opsonization have increased susceptibility to organisms for which C3b-dependent opsonization and phagocytosis plays an important role—organisms such as pneumococci, streptococci, and *H. influenzae* type b. Patients with deficiencies of C5, C6, C7, C8, or C9 are able to generate opsonically active C3b and thus have less susceptibility to these organisms.[27] However, because they lack the ability to generate C5- through C9-dependent bactericidal activity, these deficient patients are susceptible especially to *Neisseria* spp., for which bactericidal activity is a critical host defense mechanism. Between 5% and 15% of patients with systemic meningococcal infections have an inherited deficiency of a terminal component (C5–C9).[27] The risk for having a complement deficiency is higher if the infection is caused by an uncommon serotype (i.e., X, Y, and W135) or if the individual or a first-degree relative has had meningococcal infection. In-depth study of diseases, such as atypical hemolytic uremic syndrome and macular degeneration in elderly people, has uncovered a much more subtle type of complement deficiency that has not yet been explored in detail as a factor in host defense against infection.[23]

C1q Deficiency

Patients with C1q deficiency are unable to activate C3 and C5 through C9 by the classical pathway and thus have decreased antibody and C3b-dependent opsonizing activity as well as C5b- through C9-dependent bactericidal activity.[38] Interestingly, their predominant clinical presentation is a lupus-like syndrome with 75% of the relatively rare C1q-deficient individuals reported as having severe systemic lupus erythematosus (SLE). This genetic defect has the closest known association with SLE. Some patients also have contracted septicemia or meningitis caused by encapsulated bacteria.

C1r or C1s Deficiency

Patients with C1r or C1s deficiency have markedly reduced concentrations of the deficient protein (<1% of normal) and levels of the related protein that are 20% to 50% of normal.[39] Similar to patients with C1q deficiency, C1r- or C1s-deficient patients are unable to activate C3 and C5 through C9 by the classical pathway and thus have decreased C3b-dependent opsonizing activity and C5- through C9-dependent bactericidal activity. Many C1r- or C1s-deficient patients have SLE or isolated glomerulonephritis rather than infection.

Mannose-Binding Lectin Deficiency

MBL deficiency is the most common deficiency of a complement protein, accounting for up to one third of cases.[20] The normal serum level of MBL is low, 1 to 2 μg/mL. In about one third of the population, mutations in either the chain-coding or promoter regions of the gene lead to blood levels that are about ⅒ of normal. The literature suggests that individuals with MBL deficiency have a statistically increased frequency of infection, especially in the newborn period. Moreover, patients with cystic fibrosis with low MBL levels are more likely to die earlier in life from infection than are patients with normal levels, although the reasons for this are unclear. Patients with MBL deficiency may have increased frequency of rheumatologic diseases.

C4 and C2 Deficiency

C4 is encoded by two closely linked distinct loci (C4A and C4B) within the major histocompatibility complex (MHC) locus. Individuals with complete C4 deficiency are therefore deficient at both loci. As with other deficiencies of the classical pathway, C4-deficient patients do not generate C3b-dependent opsonizing activity or classical C5- through C9-dependent bactericidal activity. Serum deficient in C4 is capable of opsonization and bactericidal activity through microbial activation of the alternative pathway but not as quickly or to the same degree as serum containing C4. The most common clinical manifestation of complete C4 deficiency has been a lupus-like syndrome, and some patients have had bacterial septicemia or meningitis. Homozygous C4B deficiency predisposes children to bacterial meningitis, presumably because they need to depend on the less functionally active C4A isotype to activate C3 through the classical pathway.[36]

C2 Deficiency

Although the ability of C2-deficient patients to generate complement-dependent opsonic and bactericidal activity by the classical pathway is reduced, activity is generated by the alternative pathway.[36,40] Affected individuals may be healthy, but a subset have an increased susceptibility to infection and several rheumatologic disorders. Typical infections are septicemia or meningitis. Usual pathogens include encapsulated pyogenic bacteria such as the pneumococci and typable *H. influenzae,* pseudomonas, and meningococci.

C3 Deficiency

C3 is central to the function of all activation pathways, and C3-deficient individuals have deficient opsonic and bactericidal activity.[15,18] Affected patients typically manifest an increased susceptibility to infection and a variety of rheumatologic diseases. Localized infections, such as recurrent otitis media, sinusitis, and pneumonia, also can occur. The most common etiologic organisms are pneumococci, typable *H. influenzae,* and meningococci.

In normal hosts, iC3b interacts with CD11b/CD18 and CD11c/CD18; these receptors are deficient in patients with leukocyte adhesion deficiency.[18,41] The defect usually is in the protein CD18, and these patients are deficient in all of the B2 integrins including LFA1, known to be important in T-lymphocyte function (see Chapter 104).

C5 Deficiency

Patients with C5 deficiency can generate opsonically active C3b through activation of the classical or alternative pathway, but cannot generate C5b- through C9-dependent bactericidal activity.[18,29] They do not have an increased susceptibility to infection with encapsulated bacteria; however, because normal host defense against *Neisseria* spp. depends on intact serum bactericidal activity, C5-deficient patients have increased susceptibility to systemic *Neisseria* spp. infections.[18,27] Patients with C5 deficiency fail to generate normal C5a, which is thought to contribute to their increased risk for infectious disease complications.

C6, C7, C8, C9, and Properdin Deficiency

Patients with C6, C7, or C8 deficiency can opsonize microbes but are unable to generate complement-dependent bactericidal activity. They have an increased risk for systemic meningococcal and gonococcal infections.[36]

Native C8 is composed of three distinct chains. The α and γ chains are covalently linked to form one subunit, which is noncovalently bound to the second subunit composed of the β chain.[36] There are two genetically distinct forms of C8 deficiency, one in which the α-γ subunit is deficient, and the other in which the β subunit is deficient. Blacks tend to have C8 α-γ chain deficiency, and whites tend to have deficiency of the β chain. In both forms, C8 functional activity and serum bactericidal activity are reduced markedly. The predominant clinical expression of C8 deficiency is an increased susceptibility to systemic *Neisseria* spp. infections.[8]

The assembly of C5b through C8 results in an unstable membrane attack complex that possesses limited bactericidal activity. The first patient described with C9 deficiency had no apparent consequence. Subsequently, an epidemiologic study has demonstrated the relationship between C9 deficiency and systemic meningococcal and other infections.[42,43]

Properdin acts to stabilize the alternative pathway C3-cleaving enzyme, C3bBb, thereby retarding its intrinsic decay. Deficiency of properdin increases susceptibility to bacterial infections, particularly those caused by *Neisseria*.

Deficiency of Factors H and I

Factor H is one of a set of 5 proteins that have elements of similar structure. Factor H deficiency is associated with atypical hemolytic uremic syndrome.[44] Abnormalities in factor H also are associated with age-related macular degeneration.[45] Complement may be important in the clearance of debris from various sites of deposition, such as in the back of the eye.[45] A wide variety of microbes have been found to bind factor H specifically in plasma, thereby helping to downregulate the ability of complement to destroy the organism.[46,47] Factor I is a cofactor for the cleavage of factor H–bound C3b to iC3b. Factor I also functions with additional membrane proteins that act as cofactors for the cleavage of C3b and iC3b to form C3d. These are the C3b receptor itself (CD35) and CD46.[18,48] Patients with factor I deficiency have uncontrolled activation of C3, with resulting secondary serum C3 deficiency. Afflicted patients have an increased susceptibility to infection with the same encapsulated bacteria to which C3-deficient patients are susceptible. Patients with mutations in factor I also have increased incidence of atypical hemolytic uremic syndrome.[44]

Patients with factor D deficiency are unable to activate C3 by the alternative pathway. Rare families have been described in which patients with mutations of factor D have had systemic meningococcal infections.[36] Factor B is the protein in the alternative pathway that functions like C2 of the classical pathway; only a few instances of factor B deficiency in humans have been reported.

Secondary Deficiencies of Complement

Secondary deficiencies of complement can contribute to increased susceptibility to infection. For example, children with the idiopathic nephrotic syndrome who lose complement proteins in their urine have an increased susceptibility to pneumococcal peritonitis and sepsis.[49]

Infants

Complement proteins in general do not cross the placenta, and serum concentrations of most complement proteins in term infants are reduced to between 50% and 80% of those found in adults. Even lower concentrations are found in premature infants.[50] These deficiencies contribute to susceptibility to infection.

Sickle Cell Disease

Patients with sickle cell disease have a markedly increased susceptibility to systemic infections caused by *Streptococcus pneumoniae*.[51] Two defects in host defense contribute to this increased susceptibility: functional asplenia and a decrease in serum opsonizing activity. Deficient serum opsonizing activity is secondary to defective activation of the alternative pathway, although the exact basis for this defect is unknown.

New Research in Genetic Deficiencies

Defects in the synthesis of individual complement proteins are rare. Defects in the control proteins are far more common. An autosomal dominant defect in synthesis of functional C1 inhibitor has been known to be causal in hereditary angioedema (HAE). Type 1 HAE defects lead to low levels of circulating protein. Type 2 defects are associated with normal or elevated levels, but functional levels are low because of amino acid defects.[37] Defects in the control proteins that regulate the degradation of C3 often are associated with the development of atypical hemolytic uremic syndrome,[23] even when defects are only in heterozygous form, emphasizing the fine balance between activation and downregulation of complement. In examining the causes of glomerulonephritis in patients and in macular degeneration, it has been learned that minor alterations in either complement proteins or control proteins with small alterations in amino acid sequence can upregulate slightly the activity of complement proteins such as C3 or factor B, or downregulate slightly the activity of a control protein. The sum of a number of these small changes can upregulate or downregulate complement function, thereby causing disease.[23,45]

Diagnosis of Complement Deficiencies

Screening for deficiencies of the early components of the classical pathway (C1, C4, and C2), C3, and the terminal components (C5–C9) can be accomplished by measuring total serum hemolytic complement activity (CH50), an assay that examines the lysis of antibody sensitized sheep erythrocytes.[52,53] Deficiency of any complement protein leads to a reduction or absence of total hemolytic complement activity.

Deficiencies of factors B and D and properdin can be detected by a hemolytic assay that assesses lysis of rabbit erythrocytes mediated by the alternative pathway.[53] This assay also is abnormal in patients with deficiencies of C3 or C5 through C9. Defects of MBL can be identified by enzyme immunoassay. The specific abnormality can be confirmed by sequencing relevant genes.

In some cases the concentration of serum protein in question is a reliable test for a genetic defect. In other cases, such as in type 2 hereditary angioedema, the protein is present but nonfunctional; therefore, functional assays are needed for diagnosis. Patients with C8 deficiency lack either one (C8β) or two (C8α and γ) chains of the complete three-chain molecule. Therefore, C8 antigen is detected in the serum of such patients, but C8 function is reduced markedly. Individuals who are heterozygous for a deficiency of a single component usually have normal CH50 levels because this assay is not sufficiently sensitive to detect mild to moderate reductions in a single component.

Identification of the complement receptors or membrane-bound complement control proteins usually is established by flow cytometry.

Management

Replacement of specific components usually is not practical because of the short half-life of the complement proteins and the generation of an immune response to infused protein. Patients with complement deficiencies that predispose to an increased susceptibility to infection may benefit from the administration of prophylactic antibiotics.

Immunization against vaccine-preventable infections in complement-deficient patients is critically important. Because antibody can act directly as an opsonin through engagement of Fc receptors on phagocytic cells, increasing concentrations of specific anticapsular antibody can provide increased opsonic activity independent of complement. In addition, increased levels of specific antibody may increase activation of the classical pathway in patients with alternative pathway defects. Thus, complement-deficient individuals (see Chapter 6) should be immunized on a schedule for hosts at increased risk for *S. pneumoniae, H. influenzae* type b, and *N. meningitidis*[27] (see Chapters 6 and 126).

Infectious Complications of Dysfunction or Deficiency of Polymorphonuclear and Mononuclear Phagocytes

E. Stephen Buescher

Phagocytes perform critical roles in human host defense. Polymorphonuclear phagocytes (neutrophils, eosinophils, and basophils) defend against microbial invasion and contribute to various aspects of the inflammatory response. Mononuclear phagocytes (monocytes and macrophages) perform similar complementary functions in defense and cognate immunity. Despite their rarity, inherited disorders of these cell types provide insight into the critical role of phagocytes in human survival and health. One of the first phagocyte disorders to be recognized, chronic granulomatous disease (CGD), was described in 1957.[1,2] Despite its rare occurrence, CGD has been studied intensively and has become the paradigm for clinical management of infectious and inflammation-related problems common to disorders of phagocyte function.

Etiologic Agents

The major phagocyte function disorders and their abnormalities are outlined in Table 104.1. Because phagocytic cell responses are important both in normal host defense against extracellular microorganisms and in acute inflammatory responses, most of these conditions have the dual characteristics of recurrent infection plus deranged inflammatory responses. True pathogens or typically opportunistic agents cause infections in people with these disorders. Bacterial agents predominate in most conditions, but fungi are significant pathogens in many disorders (Table 104.2).

TABLE 104.1

Characteristic Abnormalities of Disorders of Phagocytic Function

Disorder	Characteristics of Phagocytic Cells			
	Numbers	Chemotaxis	Adherence	Microbicidal Activity
Chronic granulomatous disease	NL	NL	NL	↓
Leukocyte adhesion deficiency	↑	↓	↓	NL
Chédiak-Higashi syndrome	↓[a]	↓	NL	↓
Myeloperoxidase deficiency	NL	NL	NL	NL[b]
Specific granule deficiency	↑/NL	↓	NL	↓
Hyper-IgE–recurrent infection syndrome	NL	↓/NL	NL	NL

[a] Neutropenia is common during the accelerated phase.

[b] In vitro microbicidal activity against *Candida* spp. is deficient.

Hyper-IgE, hyperimmunoglobulin E; NL, normal; ↑, increased; ↓, decreased.

TABLE 104.2

Pathogens Associated With Disorders of Phagocytic Function

	Chronic	Leukocyte	Chédiak-	Hyper-IgE	Specific

Organism	Granulomatous Disease	Adhesion Deficiency	Higashi Syndrome	–Recurrent Infection Syndrome	Granule Deficiency	Myeloperox Deficiency
Staphylococcus aureus	++++	+++	++++	++++	+++	–
Streptococcus spp.	+	+	+++	+++	+++	–
Escherichia coli	++	+++	+	+	+	–
Burkholderia cepacia	+++	++	+	+	+	–
Serratia marcescens	+++	++	+	+	+	–
Candida spp.	++	++	+	++++	+	++++
Aspergillus spp.	+++	++	+	++	+	–
Nocardia spp.	+++	+	+	+	+	–
Pseudomonas aeruginosa	+	+++	+	+	++	–

Hyper-IgE, hyperimmunoglobulin E; ++++, most common or distinctive pathogen; +++, common pathogen; ++, less common pathogen; +, occasional pathogen; –, never associated.

Pathologic Findings

Infections can occur at any anatomic site. However, interfaces between host and environment are the sites most commonly affected; skin and soft tissue infections or abscesses, pneumonia, and infections of the upper airway or sinuses are typical (Table 104.3). Clinical manifestations depend on the nature of the underlying disorder. CGD phagocytes circulate in adequate numbers, move to tissues appropriately with normal locomotive and phagocytic function, and localize infection, but fail to develop the respiratory burst required to kill certain pathogens. As a result, abscess formation is common, but progressive, rapidly spreading cellulitis or septicemia is not. By contrast, disorders involving locomotive abnormalities (e.g., Chédiak-Higashi syndrome, leukocyte adhesion deficiency type 1) demonstrate failure to localize infection, often resulting in rapid progression of infection or systemic spread, with a delayed appearance of inflammation.

TABLE 104.3

Infectious Complications of Disorders of Phagocytic Function

	Chronic	Leukocyte	Chédiak-	Hyper-IgE	Specific

Infection	Chronic Granulomatous Disease	Leukocyte Adhesion Deficiency	Chédiak-Higashi Syndrome	–Recurrent Infection Syndrome	Specific Granule Deficiency	Myeloperox Deficiency

Abnormal acute inflammatory responses contribute to ineffective wound healing that is characteristic of these conditions. At sites of injury, histologic examination can show disordered inflammatory responses, such as combinations of acute and chronic inflammation (Fig. 104.1) or poor accumulation of inflammatory cells. In some instances, abnormal inflammatory responses, rather than infection, are the major cause of pathology.[3]

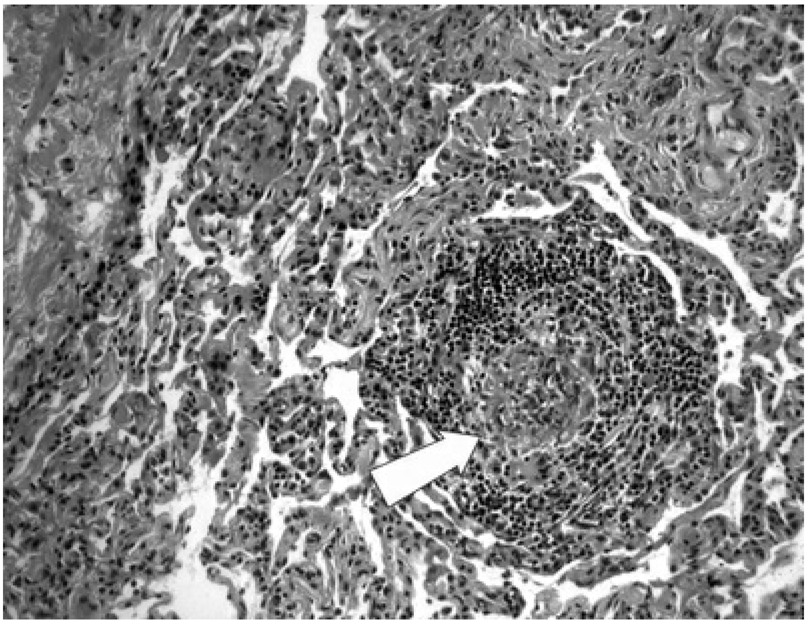

FIGURE 104.1 Pyogranuloma (acute inflammatory cells within granulomatous inflammatory response) *(arrow)* in the lung of patient with chronic granulomatous disease and *Aspergillus* spp. pneumonia.

Clinical Manifestations

Manifestations of disorders of phagocyte function are highly variable. In some instances, inflammatory (rather than infectious) manifestations occur first.[4] Age at presentation varies from neonates to adults, but presentation early in life is more typical.[5,6] Infections can be caused by well-known pathogens, opportunistic pathogens, or nonpathogens. Although few rules invariably apply, certain characteristics of infections raise concern for an underlying disorder, and specific physical findings or infectious agents may suggest specific disorders (Tables 104.2 to 104.4).

TABLE 104.4

Patterns of Clinical Illness Associated With Disorders of Phagocytic Function

Disorder	Clinical Illness
Chronic granulomatous disease	Liver abscess, aphthous stomatitis, discoid lupus erythematosus, McLeod blood phenotype, *Burkholderia cepacia* pneumonia, *Nocardia* spp. infections, *Aspergillus* spp. infections, retinitis pigmentosa, Duchenne muscular dystrophy, gastric or genitourinary tract wall thickening
Leukocyte adhesion deficiency type 1	Failure of umbilical stump separation, early periodontal disease
Myeloperoxidase deficiency	Severe infections with *Candida* spp., often in presence of diabetes mellitus
Hyper-IgE –recurrent infection syndrome	Lung cysts or pneumatoceles, soft tissue abscesses with minimal inflammation, retention of primary teeth, multiple bone fractures, scoliosis
Chédiak-Higashi syndrome	Recurrent cutaneous abscesses and cellulitis, invasive infections, progressive neuropathy, leukemia-like myeloproliferative process
Specific granule deficiency	Recurrent cutaneous and invasive infections

Hyper-IgE, hyperimmunoglobulin E.

Clinical Approach

The clinical approach to these patients involves regular, repeated examination of target organ systems, preventive therapies, and prompt evaluation of acute clinical complaints. At the time of diagnosis, studies to define the anatomy of organ systems likely to be involved with future infection can provide baseline information for comparison. These studies include scintigraphy of the skeleton and computed tomography (CT) or magnetic resonance imaging (MRI) of the chest and abdomen (liver, spleen, para-aortic nodes, kidneys, and bladder). Regular examination of the hemogram, blood chemistry, coagulation, erythrocyte sedimentation rate, and C-reactive protein values aids in monitoring the patient's general state of health and provides data for comparison during illness.

Prompt evaluation of clinical complaints permits early recognition and treatment of conditions before serious complications or tissue damage occurs. The typical inflammatory response can be absent in these patients, and fever is variable. Simple problems (e.g., hangnail, insect bite, or minor injury) can become a source of progressive infection; expectant management, with attention to local care and administration of antibiotics, is required to prevent serious complications.

Any microorganism recovered from a normally sterile site, regardless of its nominal pathogenic potential, should be regarded as a likely infectious agent. This includes normal human flora or environmental organisms when the same organism is recovered repeatedly from the same site or from multiple sites. Recovery of multiple organisms from aspiration or biopsy materials should not be discounted because polymicrobial infections (including bacteria or fungi) are well described in these patients.

Management

Identification of the Site of Infection

The ease with which sites of infection can be identified often varies from episode to episode. Skin, upper and lower respiratory tract, liver, bone, and lymph nodes are common sites of infection; spleen, gastrointestinal tract, central nervous system, and blood are less common. When the site of infection is accessible, material for culture and histology should be promptly obtained, preferably before administration of antimicrobial agents. When deep infections occur, clinical judgment must be used to decide whether antibiotic treatment can be delayed for 12 to 24 hours to acquire a surgical specimen. For patients with fever but no localizing signs or symptoms, a plan must be formulated early to define the length of clinical observation, while awaiting culture results or evolution of localizing findings, before initiating empiric antibiotic therapy. Anatomic sites previously infected should be carefully scrutinized because recurrent infections are common: bone scan and imaging studies of the chest and abdomen should be considered. Anatomic sites containing lymph nodes (hila of the lungs, paravertebral areas, mediastinum, retroperitoneum) should receive special attention because of the frequency of nodal suppuration in conditions such as CGD (see Table 104.3). Use of different imaging methods to examine the same anatomic areas (e.g., CT vs. MRI) can be helpful (Fig. 104.2). If, after 24 to 48 hours of close observation, the patient has no clinical change or has worsened, empiric antibiotic therapy should begin, usually with an antistaphylococcal agent plus an aminoglycoside or third-generation cephalosporin. In some instances, a previously unrecognized site of infection becomes evident after initiating empiric antibiotic therapy. If this occurs, appropriate surgical biopsy or drainage with culture of the specimen should be considered. Empiric antibiotic therapy alone rarely leads to resolution of unrecognized infection; repeated careful examinations of the patient and monitoring studies should be performed until the site of infection is identified or infection is ruled out.

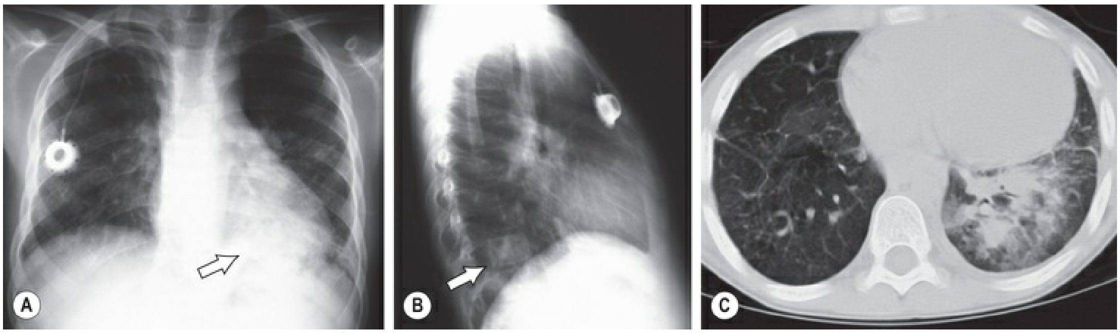

FIGURE 104.2 Chest radiograph and chest computed tomography (CT) scan of a 7-year-old child with chronic granulomatous disease with fever and dry cough. Plain films show a retrocardiac left lower lobe infiltrate *(arrow)* (A), which appears small on the lateral view *(arrow)* (B). (C) CT demonstrated more extensive disease throughout the left lower lobe. *Burkholderia cepacia* was isolated from the open-lung biopsy. Because this child had an episode of pneumonia caused by the same organism 12 months previously,

the exposure history was more intensively examined, revealing that the child had a favorite outdoor activity of pulling up wild onions.

Identification of the Infectious Agent

The importance of obtaining specimens for culture from sites of infection cannot be overemphasized; the variety of potential agents and the complicated nature of management require definitive knowledge for optimal treatment. Cultures of blood, urine, and cerebrospinal fluid (if appropriate), as well as cultures from all infected sites, should be obtained before initiation of treatment. Surgical or imaging-guided biopsy is performed for deep infection (see Fig. 104.2).

Delineation of Tissue Involvement and Debridement

For deep infections, meticulous and vigorous debridement of involved tissue should be performed at the time of biopsy; delayed control of infection, recurrence of infection, and slow healing all can result in excessive scarring and fibrosis. Tissue specimens (not swabs) should be sent for culture. For fungal infections, cure may require surgical removal of the affected tissue. Close collaboration with the surgeon, including the subspecialist's attendance at operative procedures, is required for optimal surgical intervention.

Initiation of Appropriate and Specific Treatment

When a surgical intervention is performed, prolonged postoperative drainage should be ensured by slow advancement of drains, allowing perhaps twice the usual time for drainage to be achieved. Skin and soft tissue sutures must be of maximal mechanical strength and left in place for a prolonged period because poor wound healing and weak scars in these patients lead to dehiscence. The duration of antimicrobial treatment typically is extended to approximately twice that required to treat an immunocompetent child with the same infection, with further tailoring of treatment based on the extent of disease, antimicrobial susceptibility of microorganisms, effectiveness of surgery and therapy, and complications. Intravenous therapy is the standard for acute management, with oral treatment only used for chronic phases of therapy. Central venous catheters, if used, should be managed with meticulous aseptic technique because of associated risks for infection. Defervescence in patients receiving appropriate management may be slow, but ineffective drainage, failure to identify and drain all foci, and iatrogenic causes, such as thrombophlebitis or drug fever, also must be considered when fever persists.

The frequency and severity of fungal infections, especially in patients with CGD, deserve specific comment (see Table 104.2).[7] Experience with CGD suggests that surgical resection of fungal infection offers the best chance of cure, but often, complete surgical resection is impossible. Amphotericin B, the mainstay of therapy in the past, remains effective against many fungi, but newer agents with less attendant toxicity, including itraconazole, voriconazole, caspofungin, and posaconazole, are supplanting its use.[8]

Inadequate treatment of infectious episodes is common in these patients. When infection is suppressed instead of eradicated, smoldering infection and chronic inflammation lead to end-organ damage and scarring that eventually become insurmountable clinically, negatively affecting the patient's long-term prognosis.

Aggressive conventional approaches to treatment are not always successful. Unconventional adjunctive modalities must be considered in some situations, especially for fungal infections. Administration of functionally competent leukocytes by transfusion can be considered in situations of failure of aggressively applied conventional therapies, lack of localization of an infectious process, or life-threatening infection.[9] Most experience with leukocyte transfusions is based on care of patients with CGD, often in the context of extensive, nonresectable fungal infection.[7,10] When used in this situation, it is prudent to separate leukocyte transfusion administration and infusion of amphotericin B by at least 6 hours to avoid acute pulmonary decompensation.[11] If used, it is important to understand that antileukocyte antibodies develop in approximately three fourths of patients.[12]

Inflammatory Diseases

With widespread, routine use of prophylactic antibacterial and antifungal agents, disease due to dysfunction of acute inflammatory responses in patients with CGD is more frequently recognized and reported. Inflammatory processes without obvious infection (inflammatory bowel disease–like manifestations, genitourinary and gastrointestinal tract granulomatous masses) clearly occur in these patients, and although infection should always be the primary concern, failure to identify an infectious process should lead to consideration of an inflammatory process, with management approaches shifting away from anti-infectious therapies to anti-inflammation therapies.[13]

Complications

Progressive tissue damage with associated loss of physiologic function or extension of infection is the most serious consequence of ineffective treatment of infection (Fig. 104.3). Progressive loss of pulmonary function, with parenchymal loss, bronchiectasis, and restrictive lung disease, is a typical irreversible complication, which can be minimized or avoided by prompt definitive diagnosis and aggressive management.

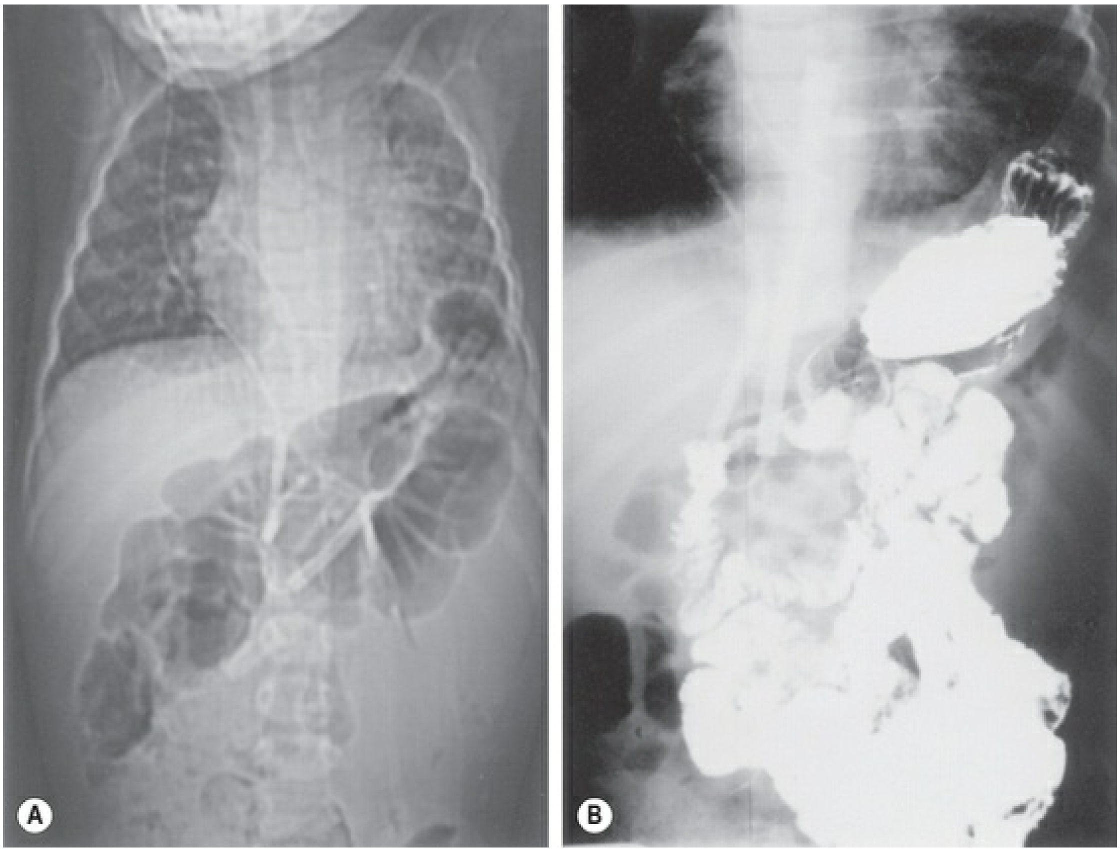

FIGURE 104.3 Plain radiograph (A) and barium study (B) illustrating herniation of the stomach through the incompetent left hemidiaphragm in a patient with chronic granulomatous disease. The left anterior chest wall, left lung, and left hemidiaphragm had been infected with *Aspergillus fumigatus* 2 years previously and had been effectively treated with white blood cell transfusions and parenteral antifungal treatment.

Effects of inflammation-related masses, wound dehiscence, and mechanical failure of scar tissue are other major complications (Fig. 104.4). In CGD, obstruction of the gastrointestinal or urinary tract by masses of granulomatous tissue, often without evidence of active infection, is a manifestation of the abnormal inflammatory response.[14,15] In some patients with CGD, gastric outlet obstruction is the first manifestation (Fig. 104.5).[14] Corticosteroid therapy is used to re-establish normal function.[13] Inflammatory bowel disease-like colitis occurs in some patients with CGD and can be difficult to control. Complications of poor wound healing generally can be avoided by careful surgical technique and delayed removal of suture material.

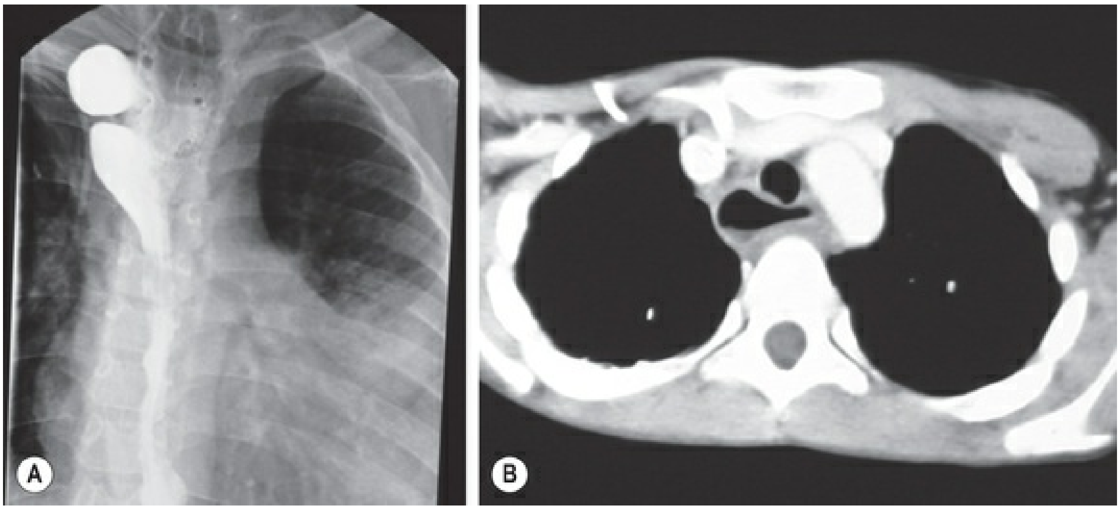

FIGURE 104.4 Barium swallow (A) and chest computed tomography (CT) images (B) of a 10-year-old patient with chronic granulomatous disease. Gastrointestinal granulomatosus was first diagnosed at 3 years of age and treated since with intermittent-pulse corticosteroid therapy for symptoms. Upper esophageal diverticulum formed spontaneously over 4 years, during which time right upper lobe aspergillosis was diagnosed and treated. At age 7 years, right upper lobe resection was performed, with subsequent development of the lower diverticulum.

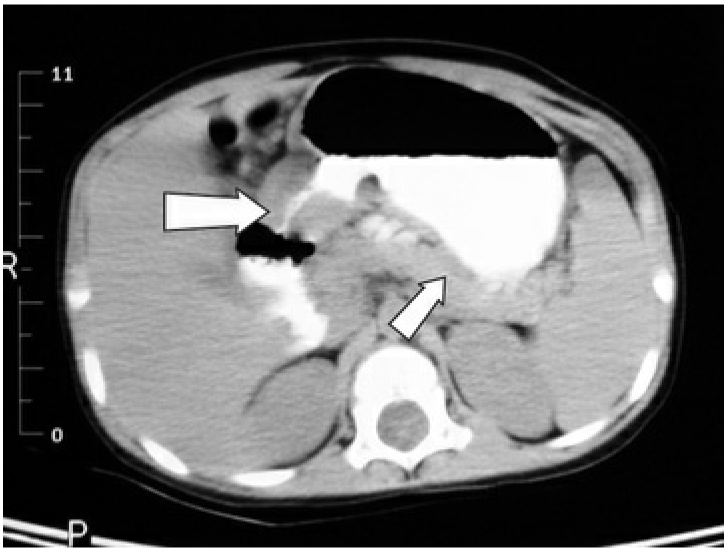

FIGURE 104.5 Abdominal computed tomography (CT) study of a 2-year-old boy with chronic granulomatous disease and persistent vomiting. Contrast material in the stomach forms an “apple-core” shadow as it passes through the pylorus *(upper large arrow),* which

is thickened by granulomatous inflammation. The posterior antral wall is also severely thickened *(lower small arrow).* Vomiting resolved within 24 hours of starting oral prednisone treatment.

Prognosis and Sequelae

The prognosis for patients with phagocyte functional disorders has improved steadily over time. With aggressive management of infections and careful follow-up, 10-year survival in conditions such as CGD has improved from 15% to 25% previously to 80% or greater.[16,17] Survival data for other conditions are not readily available. Rates of infection in patients with CGD can be reduced by prophylaxis with cotrimoxazole, itraconazole or voriconazole, and interferon γ.[18–21] Patients with CGD and fungal pneumonia or disseminated fungal infection have mortality rates as high as 45%.[7] Bone marrow stem cell transplantation has been more commonly performed since the mid-2000s in patients, including some with CGD and Chédiak-Higashi syndrome.[22,23] Gene insertion therapies have been successful in animal models of CGD, but are not available for humans.[24]

Recent Advances

Use of recombinant human hematopoietic growth factors has been examined in many phagocytic cell disorders and, in general, has not proved helpful, except in situations in which neutropenia accompanies abnormal function (e.g., glycogen storage disease type Ib).[25] Use of cytokines in nonmalignant syndromes of cytopenia (congenital neutropenia, myelokathexis) also shows some promise.[26,27]

Prevention

Prevention of infections in people with phagocyte function disorders is based on prophylactic administration of antimicrobial agents, prompt attention and care of minor injuries, and avoidance of potentially harmful environments. Chronic administration of oral antibiotics has not been examined definitively in any of these conditions. Daily cotrimoxazole appears to prolong infection-free periods in CGD but has less clear effects in other conditions (Table 104.5). Perioperative antibiotics should be administered before elective surgical and dental procedures (Table 104.6). Continuous prophylactic use of itraconazole to prevent fungal infections in patients with CGD results in significantly fewer invasive fungal infections.[19] Administration of ascorbic acid may be effective in reversing functional defects of phagocytes in Chédiak-Higashi syndrome and CGD, although beneficial effects have not been observed in all patients.[23,28,29] In several conditions, administration of recombinant interferon γ appears to prolong infection-free periods. Administration of subcutaneous interferon γ (50 μg/m^2) 3 times a week significantly prolongs periods between serious infections in patients with CGD, and long-term treatment is safe.[21] In hyperimmunoglobulin E (hyper-IgE) syndrome, in vitro interferon γ exposure alters polymorphonuclear leukocyte locomotive responses, but clinical trials have not been performed.[30]

TABLE 104.5

Prophylactic Antimicrobial Administration in Disorders of Phagocytic Function

Drug	Dose (Per Day)		
	<40 kg	>40 kg	Comments
Trimethoprim–sulfamethoxazole	5 mg/kg[a]	160 mg[a]	Penetrates phagocytes
Dicloxacillin	12–25 mg/kg[a]	500 mg[a]	Remains extracellular
Clindamycin	10 mg/kg[a]	300 mg[a]	Penetrates phagocytes
Itraconazole	100 mg	200 mg	

[a] Divided into 2 equal doses.

TABLE 104.6

Antibiotics and Dosages for Surgical Prophylaxis in Patients With Disorders of Phagocytic Function

Drug	Dose	Schedule	Alternative Drug
Cefazolin	Child: 20–30 mg/kg IV	20–30 min before cut; repeat every 2–3 hours during procedure[a] and 8 hours and 16 hours after procedure	Vancomycin: 15 mg/kg IV (over 1 hour) before cut; repeat (over 1 hour) every 8–12 hours during procedure
	Adult: 2 g IV	20–30 min before cut; repeat every 4 hours during procedure[a] and 8	Adult: 15 mg/kg IV over 1 hour before cut; repeat (over 1 hour)

		hours and 16 hours after procedure	every 8–12 hours during procedure
Gentamicin	Child: 2.5 mg/kg IM or IV	30–60 min before cut; do not repeat dose before 24 hours	Cefotaxime: Child: 50 mg/kg IV 20–30 minutes before cut; repeat every 3 hours during procedure[a]
	Adult: 5 mg/kg IM or IV	20–30 minutes before cut; do not repeat dose before 24 hours	Adult: 1 g IV 20–30 minutes before cut; repeat every 3 hours during procedure[a]

[a] To maintain blood level above minimal inhibitory concentration of target organism throughout procedure.

IM, intramuscular; IV, intravenous.

Minor wounds should be cleaned promptly and thoroughly and treated topically with an antiseptic or antibiotic agent. To minimize gingivitis and periodontal disease, oral hygiene should include twice-daily brushing of teeth with 3% H_2O_2 and baking soda. Activities or environments that might predispose to infection should be avoided, including active and passive smoking; environments containing decaying plants, vegetables, or wood (e.g., hay, sawdust, compost, garden mulch) where *Burkholderia* spp., spores of *Aspergillus* spp., or other fungi might be aerosolized (see Fig. 104.2).[31]

Specific Conditions

Chronic Granulomatous Disease

CGD is characterized by a defective or absent phagocyte respiratory burst in both polymorphonuclear and mononuclear phagocytes. Absence of the respiratory burst results in failure to produce reactive oxygen metabolites and H_2O_2. Microbicidal activity against catalase-positive bacteria and fungi is defective; recurrent, life-threatening infections with these organisms result. CGD occurs in 1:250,000 births. For initial screening, flow cytometric analysis of dihydrorhodamine 123 oxidation by blood leukocytes is used widely, but the nitroblue tetrazolium test remains rapid, relatively simple, and accurate. For confirmation, a quantitative test of the respiratory burst (superoxide assay or H_2O_2 assay) or demonstration of an appropriate gene defect is necessary.

Both infectious and inflammatory syndromes are associated with

CGD (see Table 104.2). Hepatic abscesses commonly cause fever, anorexia, and variable degrees of abdominal pain, often without abnormalities in serum transaminase levels. Abscesses can be multiple and variable in size (1 to >20 cm in diameter) (Fig. 104.6). Surgical excision is the preferred management.[32,33] Suppurative adenitis can involve a single node, multiple contiguous nodes, or multiple geographically separate nodes. Surgical excision is preferred, followed by prolonged antibiotic therapy. Pneumonia, caused by either bacterial or fungal agents, requires aggressive, early diagnostic efforts (e.g., bronchoalveolar lavage or open-lung biopsy). Fungal pneumonia initially can be asymptomatic and is difficult to eradicate; excisional biopsy should be seriously considered if pneumonia is localized discretely to one lung area. Osteomyelitis can cause fever with or without initial bone pain. Hematogenous spread or local extension from a nearby nonosseous infection can occur. Bone scan usually is diagnostic, and bone biopsy for identification of organisms should be performed. Concomitant antimicrobial prophylaxis may interfere with recovery of infectious agents, including fungi, so prophylactic antimicrobials should be held before diagnostic procedures. Vertebral osteomyelitis caused by *Aspergillus* spp. is difficult to treat and is associated with a poor prognosis.[34] Inflammatory syndromes include granulomatous changes in viscera that produce mass effects, poorly controlled inflammatory responses, poor scar formation, and slow wound healing (see Fig. 104.5).

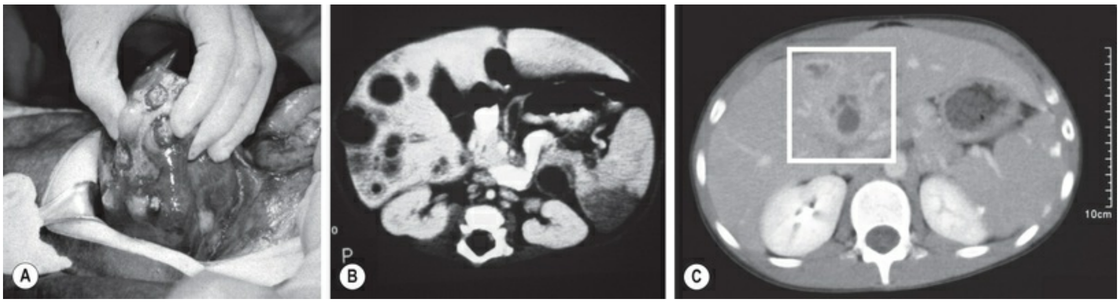

FIGURE 104.6 Intraoperative photograph (A) and abdominal computed tomography (CT) section (B) through the liver of a 3-month-old patient with chronic granulomatous disease, illustrating multiple liver abscesses, the number and location of which preclude resection en bloc. Abscesses were successfully treated using intraoperative, ultrasound-guided

aspirations, followed by prolonged antibiotic therapy. (C) Single complex liver abscess *(white box)* in a 12-year-old patient with chronic granulomatous disease. Abscess is in the medial left lobe *(box),* in contact with the portal vein. Drainage was achieved by intraoperative ultrasound-guided needle aspiration, followed by prolonged antibiotic therapy.

Myeloperoxidase Deficiency

Myeloperoxidase (MPO) deficiency is the most common syndrome of phagocyte defect, occurring in approximately 1 in 2100 persons.[35,36] MPO deficiency affects both polymorphonuclear and mononuclear phagocytes, resulting in deficient conversion of chloride and H_2O_2 to hypochlorous acid and its microbicidal byproducts. The diagnosis of MPO deficiency relies on biochemical or histochemical determination of absence of peroxidase activity in blood polymorphonuclear leukocytes. In vitro, MPO-deficient cells have only minor microbicidal abnormalities against bacterial pathogens, but killing of *Candida* spp. is dramatically deficient and may explain the severe candidal infections reported in some affected individuals.[37] Appropriate surgical debridement with antifungal treatment appears to be effective for these infections. MPO deficiency should be considered in any patient with a severe candidal infection that is not caused by an indwelling device or cytopenia.

Hyperimmunoglobulin E−Recurrent Infection Syndrome

Originally termed *Job syndrome*, hyper-IgE−recurrent infection syndrome (DOCK8 deficiency) is a multisystem disorder of at least three different forms characterized by extreme elevations of serum IgE (at least 10 times the upper limit of normal levels), recurrent skin and sinopulmonary infections, and eczematoid rashes.[38] Clinically, patients often have coarse facial features, retention of primary teeth, and candidiasis of the mouth, nails, or vagina. Recurrent sinopulmonary and cutaneous infections often begin in infancy; pneumonia frequently is severe and often is associated with pulmonary cyst or pneumatocele formation.[39,40] Bronchitis and sinusitis are common. Cutaneous infections typically are manifest as either abscesses (often with little associated evidence of inflammation) or cellulitis, but other types of cutaneous infections can occur. When osteomyelitis occurs, it is often in proximity to a soft tissue focus. Expected infectious agents include *Staphylococcus aureus*, *Haemophilus influenzae, Candida albicans, Streptococcus pneumoniae,* and *S. pyogenes,* but other organisms also are described.[41] Noninfectious manifestations include arthritis, arthralgia, multiple bone fractures, hyperextensibility of joints, scoliosis, keratoconjunctivitis, pulmonary cysts or pneumatocele, and lymphoid cancer.[38,39,42] No single laboratory study establishes the diagnosis, but extreme elevation of serum IgE level and eosinophilia are common. Most cases are associated with mutations in *STAT3* and its signaling systems.[38] Although originally proposed as a syndrome of primary phagocyte defect, it is now clear that the hyper-IgE–recurrent infection syndrome is a multisystem disease involving dentition, bones, connective tissues, and defense systems; aberrant intracellular signaling through the dedicator of cytokinesis 8 (DOCK8) protein causes the associated abnormalities of phagocyte function (i.e., chemotaxis).

Leukocyte Adhesion Deficiency Types 1, 2, and 3

Three separate conditions involving abnormalities of leukocyte adhesion are identified as leukocyte adhesion deficiency types 1, 2, and 3. The first descriptions of the condition now called leukocyte adhesion deficiency type 1 reported patients with recurrent infections, defective neutrophil mobility, and delayed separation of the umbilical cord.[43] Subsequently, the additional characteristics of severe periodontal disease, poor wound healing, and multiple adhesion-related abnormalities of phagocyte function, including poor adherence, spreading, chemotaxis, phagocytosis, and antibody-dependent cellular cytotoxicity responses, were described.[44] Partial ("moderate phenotype") or complete ("severe phenotype") absence of β_2 integrins ("leukocyte integrins," CD11/CD18) on mononuclear and polymorphonuclear phagocytic cells occur. The result is slow mobilization and poor localization of phagocytic cells at inflammatory foci, resulting in severe, systemic, life-threatening infections, often resulting in death during infancy.[44] Infections involving cutaneous ulceration, delayed wound healing, pneumonia, and peritonitis are common. Periodontal disease is common and can result in premature tooth loss. Leukocytosis without infection also is common, with marked leukocytosis often accompanying episodes of infection. Natural killer cell responses are diminished in vitro, but whether this results in abnormal cell-mediated immunity is controversial.[44] Spontaneous "regain of function" mutations in the defective β_2-integrin genes of three patients with leukocyte adhesion deficiency type 1 have been documented.[45]

Leukocyte adhesion deficiency type 2 is an unrelated disorder in which absence of fucosylated ligands (sialyl-Lewis X antigen), which are the ligands for endothelial cell selectins on the surface of phagocytes, results in ineffective phagocyte–endothelial cell interactions.[46] Associated findings are severe mental retardation, short stature, and the Bombay erythrocyte phenotype. Dietary supplementation with oral fucose reverses the adhesive defect.[47]

Leukocyte adhesion deficiency type 3 is the most recently recognized leukocyte adhesion deficiency, involving failure of integrins to respond to activation signals. Multiple mutations in the *KINDLIN3* gene have been described, with resultant defects in leukocyte adhesion and platelet aggregation. Although it is unclear presently whether the type 3 condition is one or several distinct entities, all cases recognized to date have the common clinical characteristics of recurrent infection and severe bleeding tendencies.[48]

Chédiak-Higashi Syndrome

Chédiak-Higashi syndrome is a rare, autosomal recessive disorder that results in recurrent pyogenic infections, partial oculocutaneous albinism with photophobia and nystagmus, and giant intracellular granules. Abnormal packaging of lysosomes is characteristic; all blood leukocytes show the diagnostic characteristic of abnormal, giant intracellular granules. In polymorphonuclear cells, these granules contain both primary and secondary granule markers and are deficient in elastase and cathepsin G.[46,50] In vitro, microbial killing is delayed, degranulation is abnormal, and chemotactic responsiveness is impaired.[51] Dysfunction of the lysosomal trafficking regulator gene *(LYST)* underlies the functional abnormalities of phagocytes in Chédiak-Higashi syndrome. Recurrent infections involving the respiratory tract and skin are most common, with *S. aureus* being the most common causative agent. Progressive neuropathy is common, and a lymphoma-like “accelerated phase,” accompanied by hepatosplenomegaly, lymphadenopathy, lymphohistiocytic proliferation or infiltration, anemia, neutropenia, and thrombocytopenia, develops in most patients during their first decade of life. Limited studies addressing the use of prophylaxis with antibiotic agents in these patients have shown little effect. In some patients, ascorbic acid treatment is reported to improve phagocytic cell function, but this effect does not occur in all patients.[23,28] Ascorbic acid treatment does not alter progression to the accelerated phase, prompting investigation of bone marrow transplantation to correct this syndrome.[23]

Secondary Granule Deficiency

Secondary granule deficiency is a rare condition characterized by severe, recurrent infections, and deficiency of the secondary granule marker lactoferrin due to dysfunction of the myeloid-specific transcription factor CEBPE.[52,53] These patients' phagocytes also lack all defensins, a class of phagocytic antimicrobial proteins.[50] Phagocytes from these patients have multiple functional abnormalities.[54,55] The diagnosis is made by demonstrating absence of antigenic lactoferrin in polymorphonuclear leukocytes. Clinically, patients manifest delayed localization of acute inflammatory cells at sites of injury, which leads to recurrent bacterial infections (both cutaneous and deep) and poor wound healing.[54]

Infectious Complications of Cell-Mediated Immunity Other Than AIDS

Primary Immunodeficiencies

David B. Lewis

This chapter focuses on the infectious complications of primary immunodeficiencies in which lymphocyte-mediated immunity is compromised. Genetic disorders of cell-mediated immunity that are mainly associated with hemophagocytic syndrome are discussed in Chapter 12. Acquired autoantibody syndromes that result in infectious complications that mimic inherited immunodeficiencies are included, whereas inherited immunodeficiencies that mainly result in an autoimmune diathesis rather than compromised host defense, such as FoxP3 deficiency (IPEX syndrome) or CTLA-4 haploinsufficiency,[1,2] are not discussed here.

Overview of Cell-Mediated Immunity and Its Role in Control of Infections

Disorders of cell-mediated immunity that predispose to infection can be due to quantitative or qualitative deficiencies of thymus-derived lymphocytes (T lymphocytes, T cells) or innate lymphocyte cells (ILCs), such as natural killer (NK) cells, as well as abnormalities in antigen-processing or presentation to T cells by antigen-presenting cells (APCs).[1,2] Limitations in cytokine production or cytokine responsiveness (e.g., genetic deficiencies in cytokine receptors), in downstream signaling and transcriptional regulatory molecules (e.g., JAKs [*Ja*nus tyrosine *k*inases] and STAT [*s*ignal *t*ransduction and *a*ctivator of *t*ranscription] proteins[3]), and in acquired autoantibodies to cytokines[4] are also are important causes of opportunistic and severe infections.

T cells that express a heterodimeric T-cell receptor (TCR) for antigen consisting of an α and a β chain (α/β T cells) play a critical role in the initiation and maintenance of antigen-specific immunity.[5] Most α/β T cells recognize antigens in the form of short peptides bound to histocompatibility leukocyte antigen (HLA) molecules on APCs, and this recognition involves a highly diverse repertoire of αβ TCRs that are clonally distributed on T cells. The CD4 subset of α/β T cells recognizes peptide antigens presented by major histocompatibility complex (MHC) class II molecules, which consist of HLA-DR, HLA-DP, and HLA-DQ in humans. CD4 T cells regulate the adaptive immune response by producing soluble cytokines, such as interleukin-2 (IL-2), IL-4, IL-5, IL-9, IL-13, IL-17, IL-21, IL-22, interferon γ (IFNγ), and tumor necrosis factor- α (TNF-α), and by expressing surface molecules, such as CD40-ligand (CD154), which interact with cognate ligands on other cells.[5] This CD4 T-cell regulation includes promoting B-cell responses to protein antigens (by CD4 T follicular helper [Tfh] cells secreting IL-21 and expressing CD40-ligand, which binds to CD40 on B cells), augmenting the microbicidal activity of mononuclear phagocytes (by CD4 T helper 1 [Th1] cells secreting IFNγ, IL-2, and TNF-α), enhancing the production of and tissue microbicidal activity of neutrophils (by CD4 Th17 cells secreting IL-17 and IL-22), and helping maintain CD8 effector T cells that are involved in the control of persistent viral infections. Effector CD4 T cells, especially Th1 cells, are important for the control of pathogens that infect cells for at least part of their life cycle, particularly certain bacteria (e.g., *Mycobacterium, Salmonella, Listeria*), fungi (e.g., *Pneumocystis*), protozoa (e.g., *Toxoplasma* and *Leishmania*), and viruses (e.g., herpesviruses). Effector Th17 cells are important for the control of mucocutaneous candidal infections and, based on murine studies, also may help control pulmonary infection due to gram-negative bacteria.

The human CD8 α/β T-cell subset recognizes peptide antigens presented by MHC class I molecules, which consists of HLA-A, HLA-B, and HLA-C molecules. CD8 T cells are particularly important in killing infected host cells, such as those harboring viruses, by inducing them to undergo apoptosis (cell-mediated cytotoxicity). The most important mechanism of cytotoxicity involves the secretion of perforin and granzymes from the CD8 T cell, which bind to the target cell and result in the induction of death by apoptosis.

The human α/β T-cell compartment includes additional cell populations, such as NK T cells and mucosal-associated invariant T (MAIT) cells, that express canonical or highly restricted types of αβ-TCRs and that recognize nonpeptide antigens presented by nonclassical HLA molecules. Because the importance of deficits of these human T-cell subsets, as well of γ/δ T cells, which express a TCR heterodimer consisting of an γ and a δ chain, in increasing vulnerability to infection remains unclear, they are not discussed further in detail in this chapter.

APCs are not only involved in antigen presentation but also produce cytokines, such as IL-12p70 (a heterodimer of IL-12p40 and IL-12p35 chains), IL-23 (an IL-12p40 and IL-23p19 heterodimer), and others that play an important role in directing the adaptive immune response. The CD11c$^+$ subset of dendritic cells is particularly important in initiating the immune response of naïve CD4 and CD8 T cells to viral, bacterial, and fungal pathogens. The plasmacytoid subset of dendritic cells produces very high levels of interferon type I (multiple types of IFNα and IFNβ) and may be particularly important in the early response to viruses.

ILCs are distinct from T or B cells in that they lack TCRs or B-cell receptors (BCRs), respectively. NK cells are a subgroup of ILCs that have the innate ability to kill host cells (natural cytotoxicity) that are infected with intracellular pathogens, particularly herpesviruses. As for CD8 T cells, the major pathway for NK cell–mediated cytotoxicity is secretion of perforin and granzymes. Other ILC populations lack the capacity for cell-mediated cytotoxicity but have the innate ability to secrete the cytokines characteristic of Th1, Th2, or Th17 CD4 T cells.

More than 260 monogenic primary immunodeficiency disorders in humans have been identified.[6] Most of the classical monogenic lymphocyte-mediated immunodeficiency disorders are inherited as either autosomal recessive (AR) or X-linked disorders and compromise immunity from birth (e.g., severe combined immunodeficiency [SCID]).[1,2,6] With the advent of next-generation sequencing technologies, particularly for evaluation of the exome, a growing number of primary immunodeficiency disorders have been identified that are due to heterozygous mutations and act in a dominant activating or inhibitory way ultimately to cause immunodeficiency.[6] Although primary lymphocyte-mediated immunodeficiencies collectively are rarer than acquired immunodeficiency disorders, they often manifest as unusual, severe, or recurrent infections, and they frequently require more aggressive approaches for specific microbial diagnosis and therapy. Some primary immunodeficiency disorders may require a specific infectious trigger for immunodeficiency to become manifest (e.g., Epstein-Barr virus [EBV] infection in the X-linked lymphoproliferative [XLP] syndrome).[7]

Severe Combined Immunodeficiency Syndrome

Definition

SCID, which occurs in about 1 in 58,000 live births in the United States,[8] is an inherited severe immunodeficiency with marked quantitative deficiency of the de novo production by the thymus of peripheral antigenically naïve ($CD45RA^{high}CD45RO^{low}$) T cells. The profound T-cell lymphopenia is either due to reduced intrathymic production (most etiologies) or, rarely, to a block in their egress from the thymus to the periphery [coronin 1A (*CORO1A*) deficiency].[9] The “combined” term in SCID reflects the fact that severe T-cell deficiency invariably compromises B-cell function, regardless of whether B cells are present in normal numbers, which they are in a number of common etiologies. This is because CD4 T-cell help for B-cell antibody production in the form of surface CD40 ligand and secreted cytokines, such as IL-21, is required for most antigens. In addition, in some forms of SCID the B cells that are present may have intrinsic functional defects, such as a lack of cytokine responsiveness, that further compromise B-cell function.[10] There is variable loss of NK cell numbers, depending on the specific defect (Table 105.1).[1,2,9]

TABLE 105.1

Clinical Characteristics of Some Well-Defined Forms of Severe Combined Immunodeficiency

Syndrome/Gene Defect(s)/Mode of Inheritance	Gene Product Function	Mechanism of Immunodeficiency	Effect on Lymphocyte Numbers and Function	Characteristic N –Infection-Relat Features
Common gamma chain (IL-2 receptor gamma chain) deficiency/*IL2RG*/X-linked	Component of IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 receptors	Lack of IL-7 signaling leads to ↓↓ thymocyte development; lack of IL-15 signaling arrests NK cell development	↓↓ T and NK; nl B but nonfunctional	None
JAK-3 deficiency/*JAK3*/AR	Signaling of cytokine receptors that use γc	Same as for *IL2RG* deficiency	Same as for *IL2RG* deficiency	None
IL-7 receptor α chain deficiency/*IL7R*/AR	Specific component of IL-7 receptor	Same as for *IL2RG* except that intact IL-15 function allows NK cell development	↓↓ T; nl NK and B	None
RAG-1 or RAG-2 deficiency/*RAG1* or *RAG2*/AR	Enzymes required for TCR and Ig gene rearrangement	↓↓ T- and B-cell precursors	↓↓ T and B; nl NK	None
Artemis deficiency/*DCLRE1C*/AR	Required for DNA repair process involved in TCR and Ig gene rearrangement	↓↓ T and B precursors	↓↓ T and B; nl NK	Radiation sensiti
MHC class II	Transcription	↓ Intrathymic	↓ or ↓↓ CD4	None

deficiency/*CTIIA, RFX5, RFXANK*, or *RFXAP*/AR	of MHC class II (HLA-DR, -DP, and -DQ) genes	maturation of CD4$^+$CD8$^-$ lineage cells and ↓↓ antigen presentation to peripheral CD4 T cells	T; nl or ↑ CD8 T; nl NK and B	
ZAP-70 kinase deficiency/*ZAP70*/AR	TCR signaling of thymocytes and T lymphocytes	↓ Intrathymic development of CD8$^+$ T cells; CD4$^+$ T cells have ↓↓ function	↓↓ CD8$^+$ T; nl or ↑ CD4$^+$ T; nl B and NK	None
Cartilage hair hypoplasia (CHH) syndrome/*RMRP*/AR	*RMRP* encodes an RNA that is component of mitochondria	RMRP RNA/protein required for normal thymocyte growth	↓ to ↓↓ T – SCID only occurs with severe ↓↓	Absence of scalp eyebrow hair, sh limb dwarfism
Adenosine deaminase deficiency/*ADA*/AR	Enzyme in purine salvage pathway	Thymocytes, immature B cells, and NK cells die from toxic effects of accumulated purine metabolites	↓↓ T and B in infantile-onset cases; ↓ NK cells	Rachitic flaring c costochondral junctions (50% o infantile-onset ca renal mesangial sclerosis
Purine nucleoside phosphorylase deficiency/*PNP*/AR	Enzyme in purine salvage pathway	Purine metabolites that accumulate are less toxic to B than to T cells	↓↓ T; variable ↓ in B with poor function	Central nervous system disorder autoimmune/alle disorders
Reticular dysgenesis/*AK2*/AR	Adenylate kinase 2 is an enzyme in the inner mitochondrial space required for hematopoietic stem cell development	Stem cell defect required for lymphocytes and granulocytes	↓↓ T, B, and NK ↓↓ PMNs	Bilateral sensorineural deafness
Omenn syndrome/biallelic hypomorphic deficiency of *RAG1* or *RAG2*, rarely *IL2RG, LIG4, IL7R, ADA, DCLRE1C, AK2, RMRP, ZAP70, CHD7, CARD11*	See RAG-1, RAG-2/AR	↓ T- and ↓↓ B-cell development; ↑ peripheral T cells with ↓↓ TCR repertoire	Nl or ↑ T cells with Th2 cytokine profile; ↓ regulatory T cells; ↓↓ B cells	Congenital or neonatal onset erythroderma, lymphadenopat hepatosplenome ↑↑ eosinophils a IgE

AR, autosomal recessive; B, B cell; HLA, human leukocyte antigen; Ig, immunoglobulin; IL, interleukin; MHC, major histocompatibility complex; NK, natural killer; nl, normal; ↓, moderately decreased; ↓↓, very decreased; ↑, moderately increased; PMN, polymorphonuclear leukocyte; SCID, severe combined immunodeficiency; TCR, T-cell receptor; T, T cell.

Specific Gene Defects and Their Inheritance Pattern

SCID can be due to single X-linked or biallelic AR gene defects[1,2,9] (the specific genes involved are indicated in italics) or, less commonly, to chromosomal abnormalities (e.g., complete DiGeorge syndrome).[11] Most types of SCID are due to gene defects with hematopoietic cell autonomous effects so that the disease can be cured by hematopoietic stem cell (HSC) transplantation or HSC-based gene therapy. X-linked SCID, the most common form of these hematopoietic cell autonomous defects, comprises about 50% of cases of SCID in most series and is due to deficiency of the common gamma chain gene (also known as the IL-2 receptor gamma chain gene [*IL2RG*]) encoded in the Xq13.1 region. The common gamma chain protein (CD132), along with the IL-7Rα chain (CD127), comprises the specific receptor for the cytokine IL-7, and a lack of functional IL-7 receptors on developing thymocytes results in their arrested development.[1,2,9] Deficiency of the common gamma chain protein also results in the loss of functional surface receptors for IL-2, IL-4, IL-9, IL-15, and IL-21 and compromises the ability of *IL2RG*-deficient B cells to receive IL-21–mediated help for immunoglobulin production.[7] Thymocyte deficiency of the IL-7Rα chain or of Janus kinase-3 (*JAK3*), which is associated with the common gamma chain, results in a form of SCID similar to *IL2RG* deficiency—except that these have an AR rather than an X-linked inheritance pattern.[1,2,9] SCID with an AR inheritance pattern also can be due to defects in the ability of the thymocyte TCRs to transmit survival signals to the thymocyte (e.g., deficiencies of CD3-δ [*CD3D*], CD3-ε [*CD3E*], TCR-zeta [*CD247*], zeta-associated protein of 70-kd kinase [*ZAP70*], *CD45*, or the proteins encoded by *ORAI1* or *STIM1* molecules that are involved in calcium signaling); defective thymocyte rearrangement of TCR genes (deficiencies of recombination activating gene proteins encoded by *RAG1* and *RAG2*, Artemis (*DCLRE1C*), Cernunos (*NHEJ1*), DNA ligase IV (*LIG4*), or DNA-dependent protein kinase catalytic subunit (*PRKDC*); increased thymocyte death from toxic effects of accumulated purine metabolites (deficiency of adenosine deaminase [*ADA*] or purine nucleoside phosphorylase [*PNP*]); a failure of the development of bone marrow hematopoietic cell precursors that normally colonize the thymus and give rise to thymocytes (reticular dysgenesis due to deficiency of adenylate kinase 2 [*AK2*]); and impaired expression of MHC class II molecules (deficiency of transcription factors encoded by *RFXAP*, *RFXANK*, *RFX5*, or *CIITA*), which are required for the intrathymic development of CD4 T cells from CD4$^+$CD8$^+$ thymocytes as well as antigen presentation to mature peripheral CD4 T cells.

Likely owing to variable expressivity of null mutations, AR SCID also can occur in some cases of the cartilage hair hypoplasia (CHH) syndrome[12] due to biallelic mutations of *RMRP*, (unpublished observations), which encodes an RNA involved in mitochrondrial RNA processing. SCID also can occur in some cases of immunodeficiency with multiple intestinal atresias due to biallelic mutations of the *TTC7A* gene,[13] which encodes a cytoplasmic protein that may be involved in phosphatidyl inositol signaling. Some genetic immunodeficiencies may result in substantial or even normal numbers of peripheral naïve T cells that have profound functional impairments, resulting in a SCID clinical presentation. A recent example is caspase recruitment domain 11 (CARD11) deficiency, in which there is normal production of T cells by the thymus that have profound defects in TCR activation of the NF-κB pathway.[14]

A few types of SCID are due to thymic epithelial cell abnormalities resulting in a secondary perturbation of thymocyte differentiation and proliferation. These include complete DiGeorge syndrome, which occurs in about 1% to 2% of cases of the hemizygous interstitial chromosome 22q11.2 deletion.[15] Biallelic mutations of *CHD7* (CHARGE syndrome: *c*oloboma, *h*eart defect, *a*tresia choanae, *r*etarded growth and development, *g*enital hypoplasia, *e*ar anomalies/deafness) also rarely can result in a complete DiGeorge syndrome–like clinical presentation.[16] Biallelic mutations of the gene encoding the forkhead box N1 (FoxN1) transcription factor also results in SCID due to perturbed thymic epithelial development.[1,2,9] These forms of SCID are currently treatable only by the allogeneic transplantation of thymic epithelium.[15,17]

Characteristic Infections

Even with the growing adoption of neonatal screening for SCID, it remains important for the clinician to be aware of the frequent initial presentation of SCID so that the diagnosis can be confirmed rapidly and potentially life-saving therapies, such as immune reconstitution, can be considered. SCID disorders typically manifest early in infancy with infections caused by opportunistic organisms or with severe or protracted infections caused by common pathogens, especially viruses.[9,18,19] The infectious complications of SCID are similar regardless of the particular genetic defect and reflect a failure of T cells and, in some cases, NK cells to control and ultimately eliminate intracellular viruses in these and other tissues. Infections due to adenovirus, enterovirus, parainfluenza and influenza viruses, respiratory syncytial virus (RSV), and herpesviruses, such as cytomegalovirus (CMV), herpes simplex virus (HSV), and varicella-zoster virus (VZV), can be severe, with marked pulmonary, hepatic, or central nervous system involvement.[9,18,19] Failure to thrive is a prominent manifestation in most patients and usually is due to persistent gastroenteritis from common pathogens, such as rotavirus, adenovirus, enteroviruses, or norovirus. SCID patients also have increased risk for complications from live vaccines, such as paralytic disease from oral poliovirus vaccine and diarrhea due to persistent vaccine-acquired rotavirus infection.[20]

Fungal infections, which are suggestive of severe CD4 T-cell immune deficiency, include persistent and severe mucocutaneous candidiasis and *Pneumocystis jirovecii* pneumonia (PCP). *Pneumocystis* infection always should prompt a comprehensive search for SCID or another primary immunodeficiency involving CD4 T cells.

Severe bacterial infections with pathogens that have a predominant intracellular presence, such as *Legionella, Listeria, Mycobacterium* (e.g., after vaccination with bacille Calmette-Guérin [BCG]),[21] and *Salmonella* can occur and illustrate the requirement for CD4 T-cell−mediated immunity in control of these pathogens. Other gram-negative bacteria, such as *Pseudomonas, Serratia, Klebsiella,* and *Escherichia coli,* also have been reported as causes of infection even before hematopoietic cell transplantation,[22] and this may be explained by defects in Th17 cells.[5] Some cases of SCID can be complicated before transplantation by hemophagocytic syndrome,[22] which can include neutropenia that increases the risk for invasive bacterial disease, such as gram-negative septicemia. As maternally derived immunoglobulin G (IgG) level decreases over the first several months of life, patients develop marked and persistent hypogammaglobulinemia and have increased risk for recurrent sinopulmonary infections from encapsulated bacteria, such as *Streptococcus pneumoniae* and *Haemophilus influenzae.*

Routine neonatal screening for SCID using Guthrie card blood spots for measurement of signal joint T-cell receptor excision circles (sjTRECs) is now being carried out in most states of the United States.[8] Results typically are available by approximately 3 weeks of age, after which confirmed SCID patients can be put into some form of protective isolation, treated with prophylactic antimicrobial agents to prevent infections (e.g., PCP) and begun on immunoglobulin replacement therapy. However, because CMV frequently is acquired during vaginal delivery or by breastfeeding, the current screening process will not be able to prevent the acquisition of CMV in all cases of SCID.[23]

In addition to infectious complications, some infants with SCID develop a skin rash and other organ dysfunction, such as hepatitis and gastrointestinal inflammation, from graft-versus-host-disease (GvHD). GvHD is mediated by T cells acquired transplacentally from the mother or from unirradiated blood transfusions, especially whole blood or platelets. Such maternally derived T cells also can cause hemophagocytic syndrome in untransplanted SCID patients.[22] Severe GvHD also should be distinguished from Omenn syndrome (OS), a form of SCID that classically is due to biallelic hypomorphic (i.e., not null) mutations of either *RAG1* or *RAG2*, but also can occur in cases of SCID due to other gene deficiencies, including *IL2RG*, *LIG4*, *IL7R*, *ADA*, *DCLRE1C*, *AK2*, *RMRP*, *ZAP70*, *CHD7*, and *CARD11*.[24,25] Patients with OS often have extensive erythroderma, which resembles primary dermatologic conditions, such as Netherton syndrome, lymphadenopathy, hepatosplenomegaly, and failure to thrive. OS due to hypomorphic *RAG* mutations typically includes marked peripheral eosinophilia, highly elevated serum levels of IgE, increased levels of CD4 T cells producing Th2-type cytokines (IL-4, IL-5, and IL-13), and markedly reduced peripheral CD8 T cells and B cells.[24]

About one third of infant patients with complete DiGeorge syndrome have an atypical course in which an OS-like syndrome of erythroderma that may be accompanied by enteritis and hepatitis occurs starting at several months of age.[15] The OS-like syndrome coincides with the appearance of increased numbers of circulating oligoclonal T cells that are produced by the infant (and not the mother). These T cells are highly activated, express memory/effector markers, (i.e., CD45RO^{high} CD45RA^{low}), and appear to be autoreactive against the skin, gastrointestinal tract, liver, and potentially other organs.

Diagnosis

A history of other family members who experienced severe or recurrent infections in infancy or who died of unknown cause is suggestive of the diagnosis. However, a substantial number of cases of SCID, even cases of X-linked disease, result from new mutations, in which case the family history is not informative. Because SCID usually is due to severe thymic hypoplasia, there typically is a reduced or absent thymic shadow on imaging studies. Exceptions may include *CORO1* or *CARD11* deficiency. In cases of early-onset adenosine deaminase (ADA) deficiency, lateral chest radiograph also can reveal the rachitic-like flaring of the costochondral junctions. On physical examination, peripheral lymph node tissue typically is reduced, although there are exceptions, such as in OS, in which lymphadenopathy and hepatosplenomegaly are common. In a minority of cases, findings point to a specific disorder (e.g., the findings of short-limbed dwarfism and the absence of eyebrows and hair in the CHH syndrome [*RMRP* deficiency], the absence of hair in deficiency of *FOXNI*, or the characteristic facies and congenital heart disease typical of DiGeorge syndrome; see Table 105.1).

In most cases of SCID, a complete blood count reveals a reduced absolute lymphocyte count (ALC) for age. This finding in early infancy never should be ignored, even in a well-appearing infant, because it can lead to an early diagnosis of immunodeficiency. A severely reduced ALC is typical of forms of SCID that result in an arrest of both naïve T-cell and B-cell development, such as null mutations of *RAG* or ADA deficiency. A less severely decreased ALC is characteristic of forms of SCID due to defects of *IL7R* because this spares human B-cell and NK cell development (see Table 105.1). However, the ALC in some forms of SCID can be normal (e.g., some cases of X-linked SCID, MHC class II deficiency, and ZAP-70 deficiency) or even increased (e.g., some cases of ZAP-70 deficiency and most cases of OS). Normal or increased counts may reflect a compensatory increase in one lymphocyte population that masks the loss of another (e.g., the absolute increase in circulating numbers of CD4 T cells masking the absence of CD8 T cells in ZAP-70 deficiency) or a pathologic expansion (e.g., the marked expansion of a small population of activated CD4 T cells with a limited αβ TCR repertoire in OS or of CD4 T cells or CD8 T cells in maternal engraftment or in atypical complete DiGeorge syndrome). In these pathologic expansions, these oligoclonal T-cell populations uniformly express memory/effector markers (CD45RO) rather than the CD45RA isoform of naïve T cells.[15,22,24] Gene defects in which there is retention of residual function may also result in ALCs that are normal or even elevated. Therefore, regardless of the result of the ALC or T-cell subset analysis, if SCID is suspected clinically it is critical to enlist the help of a clinical immunologist so that appropriate tests can be performed to evaluate lymphocyte subpopulations (e.g., phenotype by flow cytometry), and T-cell function (e.g., mitogen- and antigen-induced proliferation, flow cytometric analysis of cytokine secretion capacity), specific gene sequencing, αβ TCR repertoire analysis, and determination of T-cell receptor excision circles if this has not already been performed as part of neonatal screening.

Treatment

After SCID is diagnosed and appropriate blood samples for total and antigen-specific immunoglobulin levels have been obtained, immune globulin intravenous (IGIV) usually is administered pending a definitive treatment plan. All live vaccines, including oral poliovirus vaccine, rotavirus vaccine, measles, mumps and rubella, varicella vaccine, vaccinia, BCG, and attenuated influenza vaccine and oral *Salmonella* Typhi vaccine, are contraindicated. IGIV therapy obviates the benefit of vaccination with “killed” vaccines (e.g., inactivated poliovirus vaccine) by providing passive antibody. Therefore, inactivated or protein/polysaccharide component vaccines, although safe in SCID and other immunodeficiencies, typically are not administered after IGIV therapy is begun. For ADA deficiency, specific enzyme replacement with polyethylene glycol–associated ADA (pegademase [Adagen]) is available but should only be used in consultation with an experienced immunologist. For most SCID patients, the early transplantation of HSCs contained in bone marrow, peripheral blood, or cord blood, ideally from an HLA-matched relative, is standard treatment for immune reconstitution. For certain disorders, HSC gene therapy has been successfully employed for SCID due to *ADA* deficiency using gammaretroviral vectors to insert a transgene into HSC progenitors followed by administration to the patient.[26] For *IL2RG* SCID, clinical gene therapy trials are underway using self-inactivating gammaretroviral vectors and lentiviral vectors.[26] These newer vectors appear to be safe and effective and avoid the potentially serious effects of dysregulation of endogenous genes near the viral insertion site using conventional gammaretroviral vectors that led to the development of T-cell lymphoid cancers in a number of gene therapy recipients.

Pneumonia in Severe Combined Immunodeficiency Disease

Pneumonia often is a presenting feature of SCID, as well as other serious disorders of T-cell immunity. Because virtually any microorganism can cause pneumonia in these hosts, it is imperative to establish a specific etiologic diagnosis, particularly if the patient shows signs of severe disease or deterioration. Some clinicians advocate initially relying on bronchoalveolar lavage to make a diagnosis, reserving thoracoscopic lung biopsy for those who do not have a prompt response to initial therapy and who lack a specific identified agent.[27] Others argue that early lung biopsy potentially can improve patient outcome and that delay in biopsy accounts for lack of its beneficial effect on survival.[28] (See discussion at end of reference 28.)

Selected Non–Severe Combined Immunodeficiency Disease Disorders of T Cells and Natural Killer Cells

Numerous non-SCID primary immunodeficiencies of T cells and/or NK cells can manifest with serious infections.[1,2] The genetic basis, clinical features (including infection predilection, diagnosis, and treatment of some of the better characterized classic disorders), and infectious disease presentations are discussed next and summarized in Table 105.2.

TABLE 105.2

Genetic and Clinical Features of Selected T-Cell and Natural Killer Cell Immunodeficiencies

Syndrome/Gene Defect/Mode of Inheritance	Gene Product Function and Mechanism of Immunodeficiency	Characteristic Noninfectious and Immune Features	Characteristic
Ataxia telangiectasia/*ATM*/ biallelic autosomal recessive (AR)	Protects from radiation-induced chromosomal damage by cell cycle arrest, allowing DNA repair; impaired V(D)J recombination and antibody isotype switching	Progressive cerebellar ataxia, bulbar and cutaneous telangiectasia; cellular hypersensitivity to radiation; ↓ IgA, IgM, T cells	Severe sinopu infections and bronchiectasis occasionally opportunistic T-cell immun is severe
Autoimmune polyendocrinopathy–candidiasis–ectodermal dysplasia (APECED) syndrome/*AIRE*/biallelic AR	Elimination of autoreactive thymocytes in thymic medulla, which if allowed to survive can contribute to autoimmunity	Autoimmune endocrinopathies, hepatitis, vitiligo, keratopathy; ↓ Th17 and Th22 immunity due to autoantibodies against IL-17A, IL-17F, and IL-22	Chronic muco candidiasis (
DiGeorge syndrome (DGS) /interstitial deletion of chromosome 22q11.2/haploinsufficiency	Haploinsufficiency for the *TBX1* and *CRKL* genes result in hypoplasia of third and fourth branchial arch derivatives, including the thymus	Truncoconal congenital heart disease, characteristic facies, hypocalcemia; ↓ T cells (CD8 subset often ↓ more than CD4)	Usually asym T cells >500/μ DiGeorge syn (naïve CD45R T cells <50/μL manifest as S
Hyper-IgE–AD syndrome/*STAT3* /monoallelic AD	*STAT3* mutations that allow expression of mutated full-length protein inhibit the activity of STAT3 encoded by the normal allele	Eczema/dermatitis; osteoporosis, pathologic fractures, retention of deciduous teeth; coarse facies, joint hyperextensibility, aneurysms; ↑↑ IgE; ↓↓ IL-17– and IL-	*Staphylococcus* boils (↓ IL-22); pneumonia a empyema due and other bac 17); pneumat secondarily in *Aspergillus,* ot nontuberculo

		22–producing CD4 T cells	*Mycobacterium*
Hyper-IgE–AR syndrome/*DOCK8*/biallelic AR	*DOCK8* is involved in intracellular signaling and possibly in cell migration of multiple hematopoietic cell types	Eczema, dermatitis, ↑↑ IgE with allergies to drugs, foods; eosinophilia; ↓ T cells; ↓ Ig response to bacterial polysaccharides	Viral infection (HSV, VZV, H molluscum co CMC, PCP; re bacterial sino infections
Hyper-IgM syndrome/*CD154*/X-linked	Binds to CD40 and activates B cells and APCs; CD40 ligand/CD40 interaction required for generation of memory T and B cells, and isotype switching	Neutropenia and stomatitis common; normal or elevated IgM in 50% with ↓↓ serum IgG and IgA; poor specific antibody formation to protein antigens	Bacterial sino infections and parvovirus (↓ immunity); *Pr* *Cryptococcus,* *Cryptosporidiu* *Toxoplasma,* Cl T-cell immuni
IL-17 pathway disorders/*ACT1, IL17F, IL17RA, IL17RC, RORC, STAT1* (GOF), *STAT3* (AD)/mostly biallelic AR; *STAT1* and *STAT3* monoallelic	Genes of this pathway are involved in the generation and function of T cells that produce IL-17A and IL-17F	Deficiency of IL-17–producing T cells (deficiencies of *IL17F, RORC,* GOF *STAT1,* AD *STAT3*) or lack of responsiveness to IL-17A and IL-17F (deficiencies of *IL17RA, IL17RC, ACT1*)	CMC
IFNγ receptor deficiency/*IFNGR1* or *IFNGR2* genes/mostly biallelic AR	Specific cell surface receptor for IFNγ, a potent activator of mononuclear phagocytes	Poor granuloma formation in response to mycobacterial infections	Disseminated nontuberculou *Mycobacterium* *Salmonella, Lis* *Toxoplasma*; re and respirator infections?
IL-12 or IL-12 receptor chain deficiency/*IL12B* or *IL12RB1*/biallelic AR	IL-12p40 is a component of IL-12p70 and IL-23, which respectively induce Th1 (IFNγ) and Th17 (IL-17A and IL-17F) immunity by CD4 T cells	Granuloma formation in response to mycobacterial infection is normal	Nontuberculo mycobacteria, disseminated *Salmonella, Lis* (mild and onl patients)
***NEMO* mutation with immunodeficiency/*IKBKG* /X-linked hypomorphic mutations**	Impaired activation of the NF-κB transcription factor impairs innate (e.g., NK cell function) and adaptive immunity by T and B cells	Hypohidrosis; conical/peg teeth, oligodontia, delayed tooth eruption; ↓ T-cell –specific and ↓↓ specific antibody responses; ↓ NK cell–mediated cytotoxicity	Disseminated nontuberculou *Mycobacterium* positive or gra bloodstream i sinopulmonar severe herpes infections; *Pne*
NK cell	Transcription	Lack of NK cells	Severe primar

deficiency/*GATA2*/haploinsufficiency (monoallelic AD)	factor regulates Unknown; lack of NK results in initially severe herpesvirus infections until T-cell immunity develops	based on CD16 and CD56 staining; may progress to involve other cell lineages, e.g., B cells and monocytes; aplastic anemia; hemophagocytic syndrome; (HPV-induced cancers	HSV, and CM but no ↑ in rec infection with viruses; HPV
Wiskott-Aldrich syndrome/*WASP*/X-linked	Regulates leukocyte cytoskeletal function; required for normal function of T cells, B cells, and APCs, including dendritic cells	Thrombocytopenia with decreased mean platelet volume; eczema; IgA-mediated autoimmune disease; ↑ IgA and IgE, ↓ IgM and antigen-specific B cell responses	Recurrent sin infections, her infections, EB lymphoprolife disease; *Pneu* *Aspergillus,* C
X-linked lymphoproliferative syndrome/*SH2D1A*/X-linked	Lymphocyte signal transduction molecule involved in T-cell and NK cell function	Lymphoid neoplasm can occur in the absence of EBV infection (rare)	Primary EBV with fulminan hemophagocy syndrome, ne later hypogammag

AD, autosomal dominant; APC, antigen-presenting cell; AR, autosomal recessive; BCG, bacille Calmette-Guérin; CMC, chronic mucocutaneous candidiasis; CMV, cytomegalovirus; EBV, Epstein-Barr virus; GOF, gain-of-function; HPV, human papillomavirus; HSV, herpes simplex virus; hyper-IgE, hyperimmunoglobulin E; IFN, interferon; Ig, immunoglobulin; IL, interleukin; MHC, major histocompatibility complex; nl, normal; PCP, *Pneumocystis jirovecii* pneumonia; PML, polymorphonuclear leukocyte; SCID, severe combined immunodeficiency; TCR, T-cell receptor; VZV, varicella-zoster virus; ↓, moderately decreased; ↓↓, very decreased; ↑, increased; ↑↑, markedly increased.

Adenosine Deaminase and Purine Nucleoside Phosphorylase Deficiency (Late Onset)

ADA, or purine nucleoside phosphorylase (PNP) deficiency, should be considered in HIV-negative patients of any age, including adults, in whom there is unexplained lymphopenia and recurrent infections. Notable infections include recurrent sinopulmonary disease, pneumonia, bacteremia, severe local papilloma infections, and recurrent herpes zoster. Late-onset infections associated with allergic or autoimmune hematologic disorders suggest partial enzyme defects.[29]

Ataxia-Telangiectasia

Ataxia-telangiectasia (AT) is an AR progressive disorder with cerebellar degeneration and a high risk for cancer due to biallelic mutations of the *ATM* (ataxia-telangiectasia mutated) gene. About two thirds of patients also develop immunologic dysfunction, which includes reduced antibody responses to polysaccharide antigens, such as unconjugated pneumococcal polysaccharide vaccine (PPV23) absent IgA in serum, and progressive loss of T cells. Patients frequently have severe and recurrent bacterial sinopulmonary infections, which likely is a reflection of markedly decreased antibody-mediated immunity.[30] Infections typical of compromised T-cell immunity are unusual, although reduced T-cell immunosurveillance may contribute to the high risk for EBV-related lymphoma. The *ATM* gene encodes a cytoplasmic protein that helps arrest the progression of the cell cycle after radiation, allowing DNA repair to be completed before resumption of cycling. This accounts for the unusual sensitivity of AT patients to radiation-induced chromosomal breakage and the development of neoplasms. The *ATM* gene product also is required for normal rearrangement by V(D)J recombination of T-cell receptor and immunoglobulin genes. The serum concentration of α-fetoprotein usually is elevated and is a useful screening test for AT. Treatment is problematic because the immunodeficiency and neurologic disease are progressive and the risk for developing cancer is high.

Autoimmune Polyendocrinopathy–Candidiasis–Ectodermal Dysplasia Syndrome

Chronic mucocutaneous candidiasis is an invariable component of the autoimmune polyendocrinopathy–candidiasis–ectodermal dysplasia (APECED) syndrome, also known as *autoimmune polyglandular syndrome type 1*, an AR disorder. The APECED syndrome can include autoimmune-mediated hypocortisolism, hypoparathyroidism, hypothyroidism, growth hormone abnormalities, hypogonadism, hepatitis, and vitiligo as well as corneal and nail abnormalities. Chronic, intractable *Candida* infection of the oral mucosa, fingers, toes, and face is frequent,[31] and occasional patients have disseminated fungal infection. Prolonged antifungal therapy and prophylaxis are the mainstay of treatment. The APECED syndrome is due to a defect in the autoimmune regulator (*AIRE*) gene, and specific diagnosis is based on DNA sequence analysis. The *AIRE* gene is required for optimal transcription of genes encoding self-proteins by thymic epithelial cells of the thymic medulla so that developing T cells reactive with these self-proteins can be eliminated by a process known as *negative selection*. This may account for the frequent detection of T-cell −dependent autoantibodies against endocrine organ targets. The increased susceptibility to candidal infection, which often starts in early childhood, is explained at least in part by autoantibodies to the cytokines IL-17A, IL-17F, and IL-22,[32,33] all of which provide important protection against fungal infection. The rest of immunologic function usually is normal.

DiGeorge Syndrome due to Interstitial Deletions of Chromosome 22 (22q11.2 Deletion Syndrome)

Patients who are hemizygous for an interstitial deletion that includes the chromosomal 22q11.2 region typically have features of classic DiGeorge syndrome. These include moderate T-cell immunodeficiency due to reduced thymocyte production because of thymic epithelial defects; transient postnatal hypocalcemia secondary to hypoparathyroidism; truncoconal cardiovascular anomalies (found in 80% of patients), especially interrupted aortic arch, truncus arteriosus, and tetralogy of Fallot; and characteristic facial anomalies.[34] Peripheral α/β T cells appear to function normally in most respects. This probably accounts for the observation that patients with circulating T-cell counts in the range of 500 to 1500/µL usually do not show signs of immunodeficiency. In most moderately lymphopenic infants with this syndrome, the peripheral CD4 and CD8 T-cell counts normalize during the first year of life. However, the assay of antigen-specific T-cell responses is particularly important because peripheral T cells can undergo homeostatic expansion in a lymphopenic environment, giving the misleading impression that thymic function is relatively intact when actually it is substantially reduced. If such responses are normal, and the patient has a CD4 T-cell count of >400/μL, live vaccines appear to be well tolerated. Moderately lymphopenic patients are at an increased risk for autoimmune hematologic and other diseases in later childhood, suggesting that the thymic defect includes limitations in the induction of T-cell tolerance or its maintenance by regulatory T cells. A small fraction of cases (<2%) can result in severe thymic hypoplasia or aplasia, so peripheral naive (CD45RA^{high}CD62-L^{high}) T-cell counts are persistently <50/μL. These patients typically have SCID-like manifestations with severe infections (see Table 105.1). In this case, immune reconstitution by thymic transplantation[15] may be effective.

Hyperimmunoglobulin E–Autosomal Dominant Syndrome

Most cases of the hyperimmunoglobulin E (hyper-IgE)−autosomal dominant (AD) syndrome are due to heterozygosity for loss-of-function mutations of the *STAT3* gene that allow protein expression.[35] These patients have a clinical triad of markedly elevated levels of IgE, recurrent pulmonary and skin infections, and eczema (the onset of the rash typically occurs in the neonatal period). Pneumonia due to *Staphylococcus aureus* and other bacteria, such as *S. pneumoniae* and *H. influenzae,* often results in a striking amount of disease but a relative lack of symptoms, such as cough and fever. Pneumonias often are complicated by the development of empyema, pneumatocoeles, and bronchiectasis. The pneumatocoeles and bronchiectatic airways often serve as sites for secondary infection with fungi, such as *Aspergillus,* or with nontuberculous *Mycobacterium* spp. The eczematous rash usually is present in the neonatal period, and skin furunculosis with *S. aureus* is invariably part of the syndrome. The predisposition to *S. aureus* pneumonia is likely due to impaired development of Th17 cells, and the predisposition to skin infections likely reflects a lack of CD4 T cells producing IL-22 (Th22 cells).[35] Children with hyper-IgE–AD syndrome frequently also have retention of their primary teeth beyond the usual age of exfoliation and joint hyperextensibility.

They also develop coarse facies, osteoporosis, and pathologic fractures, particularly after childhood, and are at risk for a variety of vascular abnormalities, including aneurysms.

Hyperimmunoglobulin E–Autosomal Recessive Syndrome (DOCK8 Deficiency)

Most cases of autosomal recessive hyper-IgE syndrome are due to biallelic mutations of the *DOCK8* (dedicator of cytokinesis 8) gene resulting in a combined immunodeficiency with impairment of both T-cell and B-cell function.[35] DOCK8 is an intracellular protein involved in cell signaling, but its normal role in immune function remains poorly understood. DOCK8-deficient patients have markedly elevated levels of IgE, usually eosinophilia, and invariably severe eczema that is often superinfected with gram-positive bacteria, sometimes resulting in skin abscesses. Susceptibility to viral infections of the skin is characteristic, including herpesviruses (HSV, VZV), human papillomavirus (HPV), and molluscum contagiosum virus.[36] DOCK8 deficiency results in progressive loss of naïve T-cell numbers with aging due to reduced thymic output of new T cells, which is accompanied by a progressive risk for developing classic opportunistic infections, such as chronic mucocutaneous candidiasis, PCP, or cryptococcosis. B-cell function is impaired, and low total serum IgM is characteristic. The antibody responses to PPV23 is minimal, and this impaired antibody response to encapsulated organisms likely contributes to the observed susceptibility to recurrent upper respiratory tract infections, such as otitis media and sinusitis, and pneumonia due to gram-positive and gram-negative bacteria. In contrast to hyper-IgE−AD syndrome, DOCK8-deficient patients are at a high risk for developing cancer, both hematologic and epithelial, and they should be considered for early HSC transplantation.

Hyperimmunoglobulin M Syndromes

The hyper-IgM syndromes have the frequent findings of elevated serum level of IgM and low levels of other immunoglobulin isotypes, particularly IgG.[37] The classic X-linked form of disease is due to genetic deficiency in CD40 ligand, a surface protein that is expressed at high levels by activated CD4 T cells. The interaction between CD40 ligand on the CD4 T cells and the CD40 molecule on dendritic cells, mononuclear phagocytes, and B cells is essential for many adaptive immune responses, but this interaction is not required for normal T-cell or B-cell development. Patients have severe qualitative defects in B-cell function and a partial but important qualitative defect in T-cell function. Markedly reduced B-cell function frequently results in recurrent sinopulmonary infections with encapsulated bacteria and rarely results in chronic parvovirus-induced anemia or enteroviral meningoencephalitis. These patients are extremely susceptible during infancy to PCP, an indication of the importance of CD40 ligand produced by CD4 T cells in the normal control of this fungus. A variety of other infections indicative of T-cell immunodeficiency have also been reported, including hepatobiliary infection with *Cryptosporidium,* cryptococcal meningitis, disseminated histoplasmosis, oral candidiasis, disseminated toxoplasmosis, severe CMV disease, and progressive multifocal leukoencephalopathy due to JC virus. Because the numbers of T and B cells (and ALC) are normal, diagnosis requires assaying for functional CD40 ligand surface expression on activated CD4 T cells using flow cytometry. Another frequent abnormality is neutropenia, which may be due to antineutrophil autoantibodies. Oral ulcers often accompany neutropenia but can occur independently. Patients should be treated with IGIV and should receive PCP prophylaxis. Some cases of severe neutropenia may respond to treatment with granulocyte colony-stimulating factor. Prognosis is poor even with these therapies; approximately 50% of patients die by the fourth decade of life. Transplantation of HSCs from bone marrow, cord blood, or peripheral blood is curative of all features of the disease.

The hyper-IgM syndrome also can occur in an AR inheritance pattern due to biallelic CD40 genetic deficiency. This is rare but clinically indistinguishable from its X-linked counterpart except that girls and boys are affected equally. The identical immunologic phenotype and clinical consequences for CD40 ligand and CD40 deficiency is consistent with CD40 being the only biologically important receptor for CD40 ligand. Other forms of AR hyper-IgM syndrome do not result in T-cell immunodeficiency but are associated with selective B-cell intrinsic defects in isotype switching and somatic hypermutation of immunoglobulin genes. These include defects in two enzymes, activation-induced cytidine deaminase (AID), and uracil *N*-glycolyase (UNG).[37] Patients with AID or UNG deficiency are predisposed to recurrent sinopulmonary and gastrointestinal infections associated with severe antibody deficiency, but are not susceptible to severe infections with intracellular pathogens, such as PCP.

Impaired T Helper 1 Immunity

Th1 CD4 T cells produce IFNγ in response to their TCR engaging specific antigen. The secreted IFNγ binds to specific IFNγ receptors, which are heterodimers encoded by the *IFNGR1* and *IFNGR2* genes expressed on the surface or target cells, such as mononuclear phagocytes. This leads to activation of homodimers encoded by *STAT1* and the enhancement of their antimicrobial activity by STAT1-dependent transcription.[5,38] Th1 cells are derived from naïve CD4 T-cell precursors that receive critical differentiation signals from cytokines produced by dendritic cells and other APCs, particularly IL-12p70, a heterodimer that consists of a p35 and p40 subunit respectively encoded by *IL12A* and *IL12B*. IL-12p70 binds to its specific receptor, which is also a heterodimer that is encoded by *IL12RB1* and *IL12RB2*, leading to Tyk2 tyrosine kinase-dependent STAT4 activation and the induction of Tbet, a master transcription factor for Th1 differentiation encoded by the *TBX21* gene.[5,38,39] Infections with nontuberculous relatively avirulent mycobacteria or dissemination after BCG immunization are the hallmark of human Th1 immune deficiencies and have been observed in patients with mutations of *IFNGR1*, *IFNGR2*, *STAT1*, *IL12B*, *IL12RB1*, and *TYK2*.[38,40] In addition, biallelic mutations of a transcription factor encoded by the *RORC* gene have also been associated with infection with avirulent *Mycobacterium*, and in this case there is not general impairment Th1 immunity but rather a specific inability of T cells to produce IFNγ in response to mycobacterial antigens.[41] *IL12B* or *IL12RB1* deficiency predominantly presents with disseminated (extraintestinal) *Salmonella* infection, and, to a lesser degree with *Mycobacterium* infection. The exquisite sensitivity of *IL12B*- or *IL12RB1*-deficient patients for disseminated *Salmonella* infection is not completely understood but likely reflects the importance of a synergy between IL-12p70 and host defense mechanisms mediated by IL-23 (a cytokine discussed subsequently). Other infectious agents that have been infrequently noted with IFNγ receptor defects include *Klebsiella*, *Legionella*, *Listeria monocytogenes*, *Mycoplasma*, *Toxoplasma gondii*, and herpesviruses (CMV, VZV, HSV).[38] In patients with acquired neutralizing autoantibodies for IFNγ, a similar pattern of infections is observed with predominance of weakly virulent mycobacteria and, less frequently, nontyphoidal *Salmonella* infections. In addition, these IFNγ autoantibody patients have also been reported to have more frequent infections with *Penicillium*, *Histoplasma*, *Cryptococcus*, and *Burkholderia* spp. and *Toxoplasma gondii* and to have higher frequency than expected for age of both dermatomal and disseminated VZV reactivation.[4]

Impaired T Helper 17 Immunity

Activated Th17 CD4 T cells produce IL-17A, IL-17F, and IL-22. These cytokines, which are also produced by a number of other subsets of T cells, such as γ/δ T cells, and ILCs promote granulocyte colony-stimulating factor–dependent neutrophil production by the bone marrow, the induction of chemokines that chemoattract neutrophils to local sites of inflammation, and increased local epithelial expression of antimicrobial peptides, such as defensins.[5,42] Collectively, these effects provide important mucosal host defense against fungal infections, such as *Candida* spp. infections, and, based on mouse models, also may provide protection against gram-negative bacterial pneumonia. Secreted IL-17A and IL-17F homodimers and IL-17A/IL-17F heterodimers bind a specific heterodimeric receptor encoded by the *IL17RA* and *IL17RC* genes,[42] and IL-22 binds to a specific heterodimeric receptor consisting of the IL-22R1 consisting of IL-10R2 chains. Engagement of the IL-17 receptor leads to activation of the receptor-associated ACT1 cytoplasmic protein that signals through pathways, such as NF-κB, leading to proinflammatory gene expression.[42] IL-22 receptor engagement leads to the tyrosine phosphorylation and activation of cytoplasmic STAT3, which translocates to the nucleus to induce gene transcription. The differentiation of Th17 cells from naïve CD4 T cells involves a number of cytokines produced by local APCs, including IL-23, IL-1β, IL-6, and transforming growth factor-β. IL-23 is a heterodimeric cytokine that consists of the IL-12p40 subunit and a p19 subunit that specifically binds to a heterodimeric specific receptor that is encoded by *IL12RB1* and *IL-23R,* leading to tyrosine phosphorylation and activation of STAT3 and STAT4.[42] IL-23 signaling helps maintain Th17 cell identity, which depends on the master transcription factor RORγt, which is one of two isoforms encoded by the *RORC* gene.[42] The hallmark infection of genetic disorders of Th17 immunity is chronic mucocutaneous candidiasis (CMC), an infectious complication that has been observed with mutations of *IL17F*, *IL17RA*, *IL17RC*, *ACT1*, *STAT3* (see earlier section "Hyperimmunoglobulin E–Autosomal Dominant Syndrome"), *IL12B*, *IL12RB1,* and *RORC*.[41,43] In the case of *IL12B* and *IL12RB1* deficiencies, which modestly affect Th17 immunity by abrogating IL-23 signaling, CMC is relatively mild and only affects about 30% of these patients, whereas disseminated *Salmonella* is a prominent complication in most patients. The fact that disseminated *Salmonella* is not a complication of "pure" IL-17 pathway defects, such as *IL17F*, *IL17RA*, *IL17RC*, and *ACT1*, suggests that IL-23 has a special role in contributing to *Salmonella* host defense that is independent of Th17 immunity. Interestingly, gain-of-function mutations of *STAT1* that result in its prolonged nuclear localization after cytokine engagement of receptors results in impaired STAT3 signaling, reduced Th17 effector CD4 T cells, and a vulnerability to CMC as well as other fungal pathogens.[43] The mechanism by which enhanced Th1 differentiation signals block Th17 development remains unclear. Finally, acquired autoantibodies to IL-17A, IL-17F, or IL-22 also result in CMC[4,43] and are the predominant mechanism for this infectious complication in *AIRE* deficiency (see earlier section "Autoimmune Polyendocrinopathy–Candidiasis–Ectodermal Dysplasia Syndrome").

Natural Killer Cell Deficiency

A few patients of both sexes have been identified with an apparent selective and complete deficiency of NK cells.[44] This selective defect in NK cells must be distinguished from a large number of primary immunodeficiencies in which there are NK cell functional defects and normal or moderately decreased numbers of NK cells.[44] Most of these patients have presented after infancy with initially severe primary herpesvirus infections, including VZV, HSV, and CMV, requiring intravenous antiviral drug therapy. After recovery from a particular herpesvirus infection, these patients do not experience an increased frequency of recurrent infection, indicating the development of durable viral-specific T-cell immunity (D. Lewis, unpublished observations). There is a complete absence of circulating NK cells, based on flow cytometry using the $CD16^+$ and $CD56^+$ markers, and absent in vitro NK cell activity in peripheral blood samples.[44] T-cell numbers and function appear to be normal in most cases, although in at least 1 patient there was also evidence of progressive loss of B-cell dysfunction with recurrent pneumonia and a poor response to PPV23 (D. Lewis, unpublished observations). Genetic sequencing indicates that a substantial fraction of patients may have haploinsufficiency for the GATA2 transcription factor.[44] IGIV has been used for therapy because theoretically this can increase antiviral function of cells other than NK cells, such as neutrophils and monocytes.

NF-κB Essential Modulator Mutation With Immunodeficiency

The NF-κB essential modulator (NEMO) protein is encoded on the X chromosome by the *IKBK* (*i*nhibitor of *k*appa *l*ight *p*olypeptide *g*ene *e*nhancer in *B* cells, *k*inase *g*amma) gene and plays a critical role in the activation of the NF-κB protein by facilitating its release from the inhibitor of NF-κB (IκB) protein complex. NEMO immunodeficiency occurs in boys with hypomorphic mutations of *IKBK*; null mutations are lethal for the embryo. Ectodermal dysplasia, including hypohidrosis, sparse hair, conical or peg-shaped teeth, oligodontia, or delayed tooth eruption, occur in >90% of cases and reflect impaired function of the ectodysplasin A receptor, which uses NF-κB for signaling. NF-κB activation also plays a central role in both innate and adaptive immune responses, including those downstream of engagement of members of the TNF receptor family (e.g., the TNF receptor and CD40), and of the antigen-specific TCR and BCR. Thus it is not surprising that the immunologic phenotype and predilection to infectious disease complications in hypomorphic *IKBK* deficiency are complex and vary depending on the particular mutation and its location within the coding region of the gene.[45] Decreased NF-κB–dependent signaling by toll-like receptors (TLRs), which can be evaluated by measuring the production by blood monocytes of cytokines such as TNF-α in response to TLR ligands (e.g., lipopolysaccharide), is observed with many mutations,[45] This block likely compromises the activation of mononuclear phagocytes and dendritic cells by pathogens and pathogen-derived products in vivo, which explains the susceptibility to sepsis caused by a variety of bacteria, including *S. pneumoniae, H. influenzae,* and *Listeria, Klebsiella,* and *Pseudomonas* spp.[46] Severe and disseminated infections with nontuberculous *Mycobacterium* spp. also are frequent and may reflect limitations in innate immunity, such as a lack of signaling by CD40 and TNF receptors.[46] PCP, CMV colitis, and severe herpesvirus infections also have been observed. NEMO-deficient NK cells often have markedly impaired natural cytotoxic activity, which may contribute to the severity of herpesvirus infections.[46] Finally, antibody responses to T-independent antigens, such as in PPV23, almost invariably are decreased and may be the only clinically evident abnormality with some mutations. Consistent with impaired CD40 signaling by B cells, some patients have a phenotype reminiscent of deficiency of CD40 ligand or of CD40 (i.e., increased levels of IgM and low levels of IgG and IgA).[45] Poor specific antibody responses, in combination with limitations in neutrophil function, likely contribute to the risk for bloodstream and other invasive infections caused by encapsulated organisms[46] and recurrent sinopulmonary infections.

Most patients have abnormalities of TLR function, which can be screened using assays such as lipopolysaccharide-induced production of TNF-α, and decreased NK cell–mediated cytotoxicity. Genetic sequencing is important for confirmation. IGIV replacement therapy is indicated routinely because of the severity of humoral immunodeficiency. HSC transplantation is curative for the immunodeficiency component of this disorder but may not correct enterocolitis, which most likely is a consequence of epithelial cell abnormalities of NF-κB signaling.

Wiskott-Aldrich Syndrome

Wiskott-Aldrich syndrome (WAS) is an X-linked disorder characterized by thrombocytopenia with small platelets, eczema of variable severity, and recurrent or severe infections due to mutations of the WAS protein gene *(WASP)*. Frequent immune abnormalities include naïve T-cell lymphopenia, particularly for CD8 T cells; impaired Th1 immune responses and regulatory T lymphocyte (Treg) activity; decreased NK cell activity; severely depressed antibody response to PPV23; moderately depressed response to protein antigens; low serum IgM levels; and elevated serum IgA and IgE levels.[47] IgE elevation, often accompanied by eosinophilia, presumably is associated with the atopic diathesis of these patients.

WASP is widely expressed by hematopoietic cells and involved in the regulation of the cytoskeleton during cell signaling in the cytoplasm and also regulates gene transcription in the nucleus involved in the generation of Th1 immune cells.[48] WASP deficiency appears to substantially but selectively compromise the intrinsic function of T cells, B cells, NK cells, and APCs.[47] In addition to recurrent pyogenic infections, especially otitis media, patients with WASP deficiency also are at increased risk for severe infection with certain viruses, particularly herpesviruses, such as VZV, HSV, and CMV,[47] and these patients appear to be at high risk for chronic recurrent infection with acyclovir-resistant HSV. Patients with complete WASP deficiency also can develop nonviral infections suggestive of severe compromised T-cell–mediated immunity, such as PCP, invasive *Aspergillus* infections, and severe CMC. A substantial fraction of patients with WASP deficiency eventually develop autoimmune vasculitis associated with deposition of IgA-containing immune complexes that has many similarities to Henoch–Schönlein purpura. Autoimmune manifestations can include intussusception, arthritis, and nephritis. The increased risk for autoimmune disease may be multifactorial, with defective B-cell tolerance, decreased Treg activity, and dysregulated secretion of interferon type I by plasmacytoid dendritic cells as contributing factors.[47] Bleeding can be severe or life-threatening in cases with profound thrombocytopenia. Splenectomy may be helpful in raising platelet counts, but this also increases the risk for life-threatening septicemia. Patients with WASP deficiency are at high risk for developing malignancy, especially lymphomas, starting after the second decade of life.

The diagnosis usually is evident, is based on the distinct features of the syndrome, can be screened for by evaluating intracellular expression of WASP using flow cytometry, and can be confirmed genetically by DNA sequencing of the *WASP* genetic locus. Immune reconstitution by HSC transplantation is curative of all disease manifestations and appears to have the best outcome if performed early in life. Gene therapy using lentiviral vectors is a promising therapeutic alternative.[47]

X-Linked Lymphoproliferative Disease and Other Genetic Immunodeficiencies With Selective Susceptibility to Severe Epstein-Barr Virus Infection

XLP disease is an X-linked immunodeficiency of males that affects T cells and B cells and is due to a mutation in the *SH2D1A* (SH2 domain protein 1A) gene.[49] The *SH2D1* gene encodes SAP (SLAM-associated protein), a cytoplasmic protein associated with the SLAM receptor (CD150) that is involved in T-cell and NK-cell signal transduction. The immunodeficiency usually is silent clinically until primary infection with EBV results in a fatal infectious mononucleosis syndrome in about 50% to 60% of cases; a lymphoproliferative disorder, including malignant lymphoma in about 25 to 30% of cases; or persistent dysgammaglobulinemia with decreased levels of IgG in about 30% of patients. Rarely, genetically affected individuals develop either lymphoma or dysgammaglobulinemia without prior EBV infection.

The mean age at development of infectious mononucleosis is about 5 years, and infection usually is accompanied by severe hepatitis with periportal lymphocytic infiltration and bone marrow dysfunction with accompanying viral-associated hemophagocytic syndrome. In cases of hemophagocytosis, there are highly activated mononuclear phagocytes, many of which have internalized red blood cells in the bone marrow, lymph nodes, liver, and spleen (see Chapter 12). Meningoencephalitis also is common. Although there are no simple screening tests for diagnosis of this disorder, an absence of invariant NK T cells, a T-cell population that has some features of NK cells and a characteristic T-cell receptor, is suggestive but not pathognomonic of the disorder.[49] The diagnosis of XLP can be established definitively by analysis of SAP protein expression or of the *SH2D1A* gene sequence. Patients with post-EBV hypogammaglobulinemia are treated with IGIV. The prognosis without definitive treatment, such as HSC transplantation, is poor, with most patients dying before 40 years of age.

In addition to *SH2D1A* gene deficiency, there are a number of other more recently identified primary immunodeficiencies that characteristically present with severe EBV infection but not with infectious complications from other viruses. These include disorders due to mutations in the *BIRC4*, *CD27*, *CORO1A*, *ITK*, *LRBA*, and *MAGT1* genes.[50] Most of these disorders are associated with a markedly increased risk for EBV-induced lymphoproliferative disease and lymphoma.

Infectious Complications in Special Hosts

Lara A. Danziger-Isakov, David A. Rosen, Jane L. Burns, David A. Hunstad

Sickle Hemoglobinopathy

The decrease in splenic function in young children with hemoglobin SS (Hb SS) disease results in increased susceptibility to fulminant bacterial infection, especially in early childhood. Since the recognition in the 1970s that rates of septicemia and meningitis due to *Streptococcus pneumoniae* were excessive in patients with sickle cell disease,[1] and with the evolution of pneumococcal vaccines, mortality and morbidity due to pneumococcal disease have decreased substantially.[1–3] Retrospective studies reported rates of invasive infection in children 0 to 10 years of age with Hb SS disease, before licensure of pneumococcal conjugate vaccine (PCV), to be 63.4 cases per 1000 person-years. More striking, mortality rates due to pneumococcal infections in US children with Hb SS disease were as high as 100 times that in the general population.[4] Patients with less severe hemoglobinopathies (sickle cell hemoglobin C [Hb SC] disease, sickle cell thalassemia [Hb S-thalassemia]) appear to have risk for severe pneumococcal disease that is lower than patients with more severe hemoglobinopathies, although still higher than that of otherwise healthy children.[5,6] Bone and joint infections are relatively more common in patients with hemoglobinopathies, and *Salmonella* spp. are isolated from these infections with greater frequency.[7,8]

Etiologic Agents

Encapsulated organisms such as *S. pneumoniae, Haemophilus influenzae* type b (Hib), *Neisseria meningitidis,* and *Salmonella* spp. are historically among the most common pathogens in patients with sickle cell disease.[9,10] In African countries, infections with *Staphylococcus aureus, Escherichia coli,* and *Salmonella* and *Klebsiella* spp. predominate, and *S. pneumoniae* is responsible for fewer cases of infection than previously reported.[11] The incidence of Hib infections in the United States has dropped to very low levels since the introduction of Hib conjugate vaccines in infancy.[12] Other microbes with special significance for patients with Hb SS disease are *Edwardsiella tarda,*[13] *Yersinia enterocolítica,*[14] *Mycoplasma* spp.,[15] *Chlamydophila* spp.,[16,17] and parvovirus B19.[18,19]

Epidemiology

Several studies of the natural history of Hb SS disease in the US, Saudi Arabia, and Jamaica have demonstrated increased mortality in young children: rates of pneumococcal infection have been 20-fold to 100-fold higher than in unaffected children in the first 5 years of life.[4,20] A study in Kenya reported an age-adjusted odds ratio for bloodstream infection (BSI) in children with Hb SS of 26 (95% confidence interval [CI], 14–48), with pneumococcus, *Salmonella,* and Hib disease documented most commonly.[21] Persistence of fetal hemoglobin is associated with fewer episodes of infection. Nasopharyngeal carriage rates and serotypes of pneumococci infecting children with Hb SS disease have been similar to those infecting unaffected hosts.[3,22] Due to the frequent use of antimicrobial agents, close contact with many children in group childcare, and penicillin prophylaxis, up to 72% of the pneumococci colonizing children with Hb SS disease are penicillin nonsusceptible.[23,24]

Although infection was the major cause of death in a cohort of patients between the ages of 1 and 3 years with Hb SS who were monitored from 1979 to 1989, cerebrovascular accidents and trauma were more common causes in those older than 10 years.[25] Other life expectancy studies suggest that at least 50% of patients with Hb SS currently followed survive beyond the fifth decade and that mortality most often is related to renal failure, chest syndrome, or stroke rather than infection.[26,27] Overall mortality associated with BSI in children with Hb SS has been documented as up to 23%, with median survival estimated to be <5 years of age.[11]

The incidence of bacterial infection in Hb SC disease, although greater than that in healthy children, is less than that in Hb SS disease. Functional asplenia has been documented in adults with Hb SC by radionuclide liver-spleen scans or by quantification of pitted erythrocytes. In one series, 4 of 51 children with Hb SC observed for 370 person-years were found to have 7 serious but nonfatal bacterial infections.[5] A second report describes 7 fatal episodes of pneumococcal septicemia in patients aged 1 to 15 years with Hb SC.[6]

Pathogenesis and Pathology

The increased incidence and morbidity of infections due to encapsulated microorganisms in patients with sickle hemoglobinopathies are attributable primarily to splenic dysfunction. The spleen is important as a reticuloendothelial filter and is involved in processing bacterial antigens to promote helper T-lymphocyte and B-lymphocyte responses. Encapsulated organisms cannot be phagocytosed efficiently without opsonization; thus, presence of type-specific antibody is critical to clearance of organisms. The spleen and the liver (to a lesser extent) are important in clearing pneumococci from the blood. Additionally, activation of complement by the alternative pathway, critical for phagocytosis in the absence of specific antibody, may be altered in patients with Hb SS.

S. pneumoniae itself elicits a profound inflammatory response. Pneumococcal cell wall fragments trigger the expression of interleukin-1 and tumor necrosis factor, cytokines that in turn mediate systemic reactions associated with the clinical syndrome of septic shock. Thus, inability of the functionally asplenic, nonimmune child with Hb SS to phagocytose and efficiently kill pneumococci results in bacteremia, multiple metastatic foci of infection, and unremitting upregulation of inflammatory mediators.

Clinical Manifestations

The clinical manifestations of infection (i.e., fever, pain, erythema, swelling) are no different from those in hosts without hemoglobinopathy. Differentiation of symptoms due to vaso-occlusive ischemia from those due to infection (e.g., osteomyelitis) remains problematic, and even advanced imaging sometimes is insufficient to discriminate between diagnoses. Children with Hb SS who appear “ill” should be treated aggressively for presumed infection and sepsis while a specific diagnosis, including meningitis, is sought.

Pulmonary Symptoms.

Bacterial pneumonia caused by *S. pneumoniae* is suspected in a patient with fever, cough, chest pain, sputum production (older patients), and abnormal chest radiograph (lobar infiltrate or other parenchymal or pleural abnormalities). Patients often appear toxic. Laboratory findings include leukocytosis, frequently with an increase in immature forms. Additional causative agents include other encapsulated bacteria, *Mycoplasma pneumoniae,*[28] and *Chlamydophila pneumoniae,*[17] all of which have been shown to cause excessive morbidity in patients with sickle hemoglobinopathy.

Acute chest syndrome, described as fever and new pulmonary symptoms in a patient with Hb SS or Hb SC, commonly is precipitated by fat embolism and infection, usually community-acquired pneumonia.[29,30] Specific causes may be difficult to differentiate.[29,31] Patients have chest pain, rales on auscultation, and infiltrates caused by focal vaso-occlusive necrosis or frank pulmonary infarction, although the latter may be less frequent in children. Radiographic abnormalities can be minimum during the first few days of symptoms. Precipitating infections are bacteria, *Chlamydophila,*[17] and viruses (especially influenza).[32] In contrast, primary vaso-occlusive crisis involving ribs can cause splinting, diminished pulmonary clearance, and secondary bacterial pneumonia.

Laboratory data helpful in differentiating bacterial infection from vaso-occlusive processes are increased band count and either extremely high or low white blood cell count (>30,000 or <5000 cells/mm^3).[33] Blood gas determinations in patients with acute pneumonia show oxygen desaturation, but patients with acute chest syndrome due to vaso-occlusion also can exhibit abnormal blood gases as a result of ventilation-perfusion mismatch. Patients with significant vaso-occlusive pulmonary disease require prompt treatment with transfusion or exchange transfusion.

Central Nervous System Symptoms.

In 1971, Barrett-Connor calculated that children with Hb SS had a 300-fold higher risk for pneumococcal meningitis than unaffected children.[1] Children with Hb SS in industrialized countries have a 6% to 8% chance of experiencing bacterial meningitis, and those in Africa have a 19% risk.[21] Of all children with Hb SS infected with *S. pneumoniae* in the pre-PCV era, meningitis developed in 20%, and 15% of these children died.[4] Factors historically associated with death in children with Hb SS and Hb SC included age >4 years, serotype 19F *S. pneumoniae,* and not being followed by a hematologist.[4] However, a significant decline in the rate of pneumococcal meningitis was documented in the 1980s, and this rate has been reduced further in recent years by the use of prophylactic penicillin in young children with Hb SS, immunization with PCV7 and PCV13, and prompt use of antimicrobial agents for febrile illnesses.[3,25,33,34] Current rates of invasive pneumococcal infection in children with Hb SS and fever probably are ≤4%.[35]

Lumbar puncture should be performed immediately in all febrile children with Hb SS who appear ill. This practice is particularly important in infants whose mental status can be difficult to evaluate and in children who have received oral antibiotics that can mitigate or delay signs of serious infection. In children with Hb SS, the incidence of overt central nervous system (CNS) vaso-occlusive disease (stroke) has been reduced to ~1%, and this condition typically manifests with neurologic abnormalities in the absence of signs of infection.[36] The management of pneumococcal meningitis includes consideration of early adjunctive corticosteroid therapy in an attempt to decrease the CNS inflammatory response.

Bone and Joint Infections.

Bone and joint infection frequently is associated with bone ischemia and can manifest as dactylitis (in infants), pyogenic arthritis, or osteomyelitis, with erythema, swelling, and pain.[7,8] An infectious cause sometimes is suggested by the clinical presentation (e.g., as a complication of septicemia due to *S. pneumoniae* or a subacute presentation with less systemic illness due to *Salmonella*). Limp or refusal to bear weight may be the only clinical complaint. Bone and joint infections are associated most often with *S. aureus*, as in unaffected children. *Salmonella* spp., including serotypes associated specifically with bone and joint infections *(S. enterica* [formerly *choleraesuis*], *S. heidelberg),* also are important because of splenic dysfunction and can manifest either as systemic infection or with localized signs and symptoms.[37] Blood and stool specimens, as well as aspirates from infected sites, should be obtained for culture before empiric antibiotic therapy is begun. It is important to determine specific etiology and antimicrobial susceptibility because prolonged therapy generally is required.

Clinical differentiation between osteomyelitis and vaso-occlusive ischemia in the bone is difficult. Pain and tenderness out of proportion to physical findings, bilateral or symmetric involvement, and diffuse (as opposed to focal) symptoms over the diaphysis or the diaphysis and metaphysis of long bones (or dorsum of the hands and fingers in infants) may indicate infarction. Laboratory findings may be helpful. Elevated erythrocyte sedimentation rate (which usually is depressed in Hb SS) suggests bacterial infection, whereas leukocyte count and C-reactive protein level can be elevated during infarction. Bony destruction (“crumbling-bone disease”) and periosteal new bone formation visualized on plain radiograph can occur with either condition. Needle aspiration of involved bone, or open bone biopsy, often is necessary to establish a definite bacterial cause. Imaging studies can be useful in establishing an etiology, but differentiation of infarction from infection remains difficult in some cases (Fig. 106.1). Magnetic resonance imaging can identify a subperiosteal fluid collection that signifies osteomyelitis and can distinguish bone from muscle involvement.[38] In addition, higher fat-saturated T1 signal intensity has been proposed as a sensitive finding in bone infarction.[39] Ultrasound has been proposed as another helpful modality.[40] However, definitive studies (e.g., prospective imaging and universal sampling for microbiologic confirmation) have not been performed. Radionuclide bone scanning is difficult to interpret in this context and is infrequently useful.

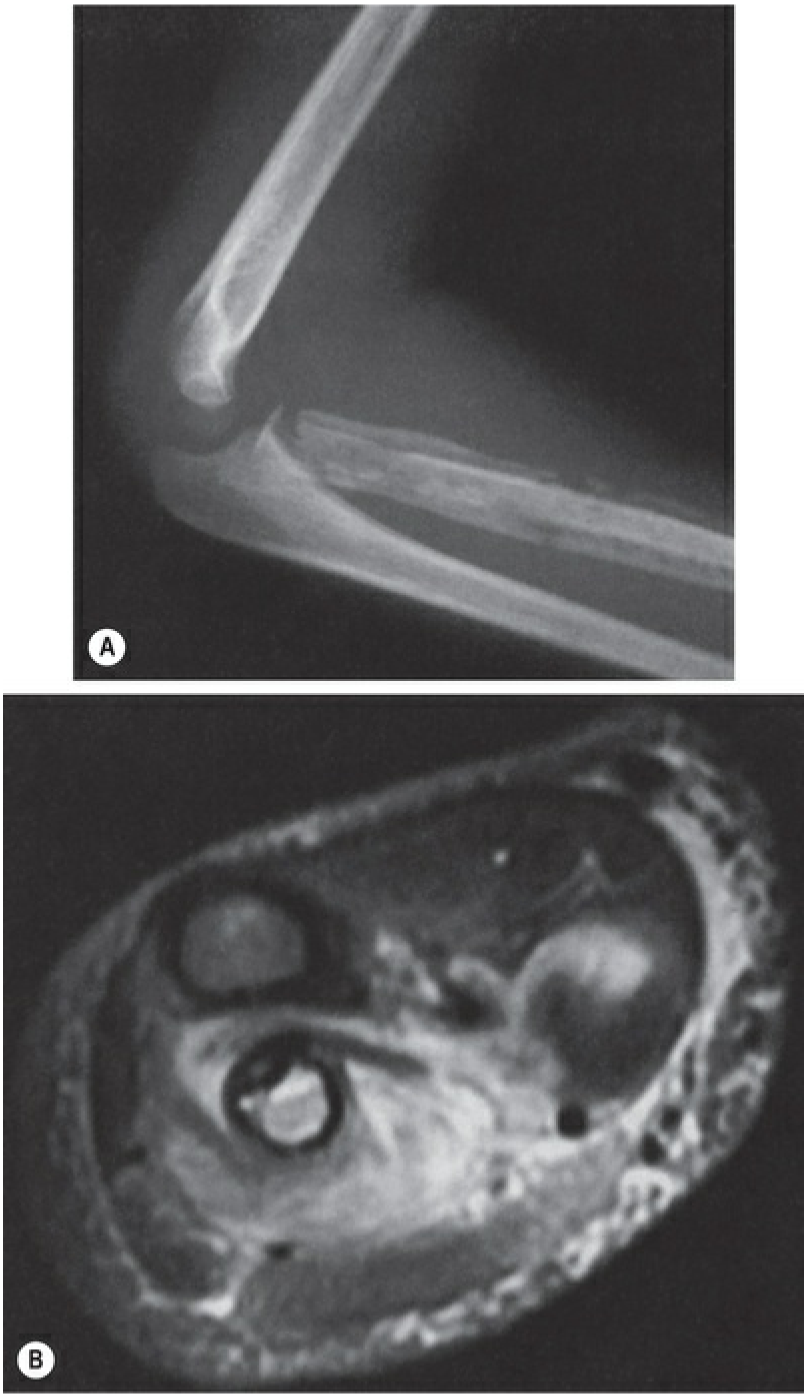

FIGURE 106.1 (A) Radiograph of elbow of 30-month-old patient with hemoglobin SS disease and osteomyelitis due to *Salmonella* spp. There is joint effusion, marked destruction of bone, involucrum, and periosteal new bone formation. (B) Magnetic resonance imaging of elbow showing fat-saturated T_2-

weighted image in the axial plane. There is joint effusion, edema of the supinator muscle, and an active process within the radius more consistent with osteomyelitis than with infarction.

Management and Presumptive Therapy

Meningitis, Septicemia, and Pneumonia.

Infants and young children with Hb SS and fever should be evaluated and treated for presumed bacterial infection. Initial evaluation usually includes a complete blood cell count, blood culture, and chest radiograph, particularly in young children in whom the physical examination may not be optimal. Patients who are at high risk for infection (i.e., those who look ill and who have a body temperature >40°C or a white blood cell count >30,000 or <5000 cells/mm^3) are more likely to have systemic bacterial infection and should be hospitalized for aggressive therapy.[33] Children who have had previous episodes of pneumococcal BSI are at increased risk for repeated infection and warrant special consideration.[41]

Patients who are febrile but do not appear ill have been managed successfully in a variety of ways, including (1) observation in a short-stay area of the hospital for several hours after institution of antimicrobial therapy and (2) parenteral administration of ceftriaxone and close observation on an outpatient basis.[33] Enthusiasm for the latter approach is tempered by case reports of severe and rapidly fatal immune-mediated hemolysis due to ceftriaxone in patients with Hb SS and in other patients who have received multiple courses of the drug.[42,43] All febrile children with Hb SS should be given an antibiotic. In the case of disease that is highly likely to be a vaso-occlusive crisis, therapy can be given orally with close follow-up.

S. pneumoniae that is nonsusceptible to penicillin or cephalosporins poses a particular challenge,[23,44,45] especially for children younger than 3 years who are receiving penicillin prophylaxis. Most commonly, vancomycin plus a third-generation cephalosporin is considered presumptive therapy for BSI (i.e., pending culture and susceptibility results). Fluoroquinolones may be considered for therapy in developing countries where widespread antibiotic resistance is present.[21] For meningitis, particularly when corticosteroids are used, vancomycin (60 mg/kg/day) plus cefotaxime or ceftriaxone is given empirically.

Bone and Joint Infections.

Empiric therapy for bone or joint infection includes agents effective against *S. aureus* (e.g., oxacillin, nafcillin, vancomycin) and *Salmonella* (e.g., third-generation cephalosporin or fluoroquinolone) as well as surgical consultation. Extensive disease, particularly that due to *Salmonella* spp., usually requires debridement and prolonged antimicrobial therapy (e.g., ≥6 months), as for chronic osteomyelitis.

Prevention

The widespread use of PCV has drastically reduced incidence of pneumococcal disease in children. The 13-valent (PCV13) series is recommended for all children, beginning at 2 months of age (see Chapter 123), including those with Hb SS.[46–49] PCV given in infancy decreases nasal colonization with *S. pneumoniae* as well as invasive disease.[50] For children with Hb SS who have previously received a complete course of the 7-valent PCV vaccine, one dose of PCV13 is given.[49] For children with Hb SS or other causes of functional asplenia, 23-valent pneumococcal polysaccharide vaccine (PPSV23) also should be given after the PCV series, at >24 months of age.[46,49] One additional dose of PPSV23 should be given 5 years after the first dose.[46,49] A quadrivalent meningococcal conjugate vaccine (MCV4) series also is recommended for children with Hb SS or Hb SC disease beginning at 2 months of age, with booster 3 years after completion of the primary series and then every 5 years.[51–53] Group B meningococcal (MenB) vaccine series also is given to children with sickle cell disease starting at 10 years of age.[54] Influenza vaccine should be targeted annually for children with Hb SS (as well as for all children 6 months and older)[48] because of the significant risk for complications due to influenza, including invasive pneumococcal infection.

Substantial reduction in morbidity and mortality due to *S. pneumoniae* has been demonstrated in children younger than 3 years with Hb SS through the use of prophylactic penicillin.[3] The major placebo-controlled study (performed before availability of PCV) demonstrated a decrease in the rate of pneumococcal infection from 9.8 to 1.5 per 100 patient-years.[34] Prophylactic penicillin is begun at 3 months of age. There is no consensus regarding the age at which prophylaxis should be stopped, but studies do not indicate benefit of continuing beyond 5 years of age.[55,56] Adherence to an oral regimen may be erratic; monthly injections of penicillin G benzathine are efficacious.

Special Considerations

Parvovirus B19 Infection.

Transient aplastic crisis in Hb SS disease (worsening anemia and profound reticulocytopenia) has been associated with parvovirus B19 infection.[18] The cellular receptor for this virus is the blood group P antigen, explaining the tropism of the virus for erythroid progenitor cells; viral infection appears to trigger apoptosis.[57] Serologic studies of patients with Hb SS who have transient aplastic crisis demonstrate acute parvovirus B19 infection in >70%.[18,19,58] Patients have a high burden of virus, are highly contagious, and do not demonstrate the characteristic rash of erythema infectiosum. Neither chronic nor recurrent disease is reported in this patient group, and anti-B19 immunoglobulin G (IgG) antibodies remain detectable for several years after infection, suggesting protection.

Asplenia and Polysplenia

Asplenic patients have increased risk for overwhelming, life-threatening infections, most commonly due to *S. pneumoniae*.[59–62] The level of risk appears to correlate inversely with the amount of time a patient has had a functioning spleen. Adults who undergo splenectomy after trauma have a lower risk for serious infection than infants with congenital asplenia syndrome and children who undergo splenectomy after trauma. Children who undergo splenectomy as part of treatment for malignancy are at great risk. Overall, approximately 3% of children whose spleen is removed before the age of 4 years have significant infections, with a mortality rate of about 40%.[63] Risk for infection is greatest in the year after splenectomy (regardless of age) and continues to be significant for the next 7 to 10 years, after which time risk is low but never as low as for people with normal splenic function.

Children with congenital asplenia and polysplenia syndromes are at increased risk for overwhelming septicemia.[64,65] Splenic function should be evaluated in children with congenital abnormalities of embryonic lateralization, such as heterotaxy syndromes involving a variety of abnormalities across the left-right axis of the body (i.e., situs inversus)[64] and a wide variety of cardiac defects including conotruncal abnormalities, transposition of the great vessels, and endocardial cushion defects. Asplenia and polysplenia often are associated with other types of congenital abnormalities, including gastrointestinal malformations such as biliary atresia, neural tube anomalies, genitourinary defects, skeletal defects, and bronchopulmonary defects, such as Kartagener syndrome, as well as bilobed and mirror-image lungs. Isolated congenital asplenia also occurs in rare kindred, with an autosomal dominant inheritance pattern.[66] Success with living-donor liver transplantation in children with polysplenia syndrome has translated into more of these high-risk patients surviving. The polysplenia syndrome also has been reported as an incidental finding on computed tomography in adults, suggesting that some individuals may have immunologic impairment that is not as significant as that of asplenic patients.

Functional asplenia is confirmed by the presence of Howell-Jolly bodies in a peripheral blood smear (obtained after the first week of life), absence of splenic uptake on a technetium-99m sulfur colloid scan, or increased percentage (>3.5%) of pitted or pocked erythrocytes in peripheral blood. The last test is not widely available but is useful in monitoring splenic function after trauma and partial splenectomy because the pocked erythrocyte count rises to >10% with absent splenic function.[67] Of note, although abdominal ultrasound readily identifies the normal or enlarged spleen, it is not 100% sensitive in patients with asplenia or polysplenia.[68] Children with severe or repeated pneumococcal infection should undergo evaluation of splenic function as well as tests for immunoglobulin deficiency and HIV infection.

Etiologic Agents

Encapsulated organisms represent the greatest risk for asplenic patients. *S. pneumoniae* has been associated with 50% to 90% of the overwhelming infections occurring after splenectomy. Other pathogens are *H. influenzae* type b and *N. meningitidis*. Fatal cases frequently are associated with meningitis.[61] It is not well documented that *N. meningitidis* infection is more fulminant in asplenic patients. Other streptococci, such as *Streptococcus agalactiae* (group B streptococcus) and *Enterococcus* spp., can cause fatal infection in asplenic hosts. Infections due to *Salmonella* spp. have been reported in asplenic patients, although the risk appears lower than with sickle hemoglobinopathy. Fulminant septicemia due to *Capnocytophaga canimorsus*, part of the mouth flora of dogs, occurs in asplenic patients, whose contact frequently is merely with a pet's saliva.[69] Asplenic patients also have substantially higher risk for infection due to *Babesia microti,* an intraerythrocytic parasite endemic in coastal areas of the northeastern US. There is increasing concern that asplenic patients are at greater risk for severe infection from *Plasmodium* spp. because the spleen plays a central role in parasite clearance.[60,70]

Pathogenesis

The central roles of the spleen include (1) mechanical clearance of antigen and foreign material; (2) synthesis of factors that enhance phagocytosis; and (3) coordination of interactions of the T-lymphocyte and B-lymphocyte responses to organisms. The spleen is important in the *initial* response to a pathogen, perhaps as a result of its role in IgM production; the asplenic host is therefore at a disadvantage when encountering a polysaccharide antigen (e.g., pneumococcal capsule) for the first time. Asplenic patients are unduly affected by encapsulated organisms that require antibody and complement for opsonization and clearance. In the absence of preformed antibody, the spleen is critical in clearing the bloodstream. This may explain why adults who have developed a broad immunologic repertoire and older children who have been given pneumococcal vaccines, and then undergo splenectomy, have a lower risk than asplenic children for overwhelming infection.[60] Infants with congenital asplenia have profoundly impaired reticuloendothelial clearance mechanisms. Additionally, they have diminished T-lymphocyte responsiveness to a variety of antigens compared with age-matched controls.[71]

Management

Seemingly trivial febrile illnesses can herald life-threatening pneumococcal septicemia in the asplenic patient. Bacterial sepsis in a cohort of patients with visceral heterotaxy and asplenia has been reported to carry a 44% mortality rate.[64] Febrile episodes require careful evaluation and empiric antibiotic therapy. Many physicians instruct patients to begin taking oral antibiotics at the earliest signs of infection, particularly if medical evaluation is not available immediately. For patients requiring parenteral antibiotics, empiric therapy is the same as for patients with Hb SS disease, typically comprising vancomycin and a third-generation cephalosporin.[72]

Prevention

Routinely recommended immunizations, especially PCV13 and PPSV23, should be given on schedule as for patients with Hb SS.[46,49] Hib conjugate vaccine and varicella vaccine are critically important for all asplenic children.[73] The series of meningococcal conjugate vaccine (MenACWY) should be begun as early as 2 months of age,[51,52] and the series of MenB vaccine and boosters is begun at 10 years of age.[74] When splenectomy is elective, patients should be fully immunized at least 2 weeks (or 4 weeks for live virus vaccines) before surgery.[75]

It is less clear whether children with asplenia benefit from prophylactic antibiotics to the same extent as children with Hb SS. Most experts recommend penicillin prophylaxis for (1) children who have congenital asplenia; (2) children who undergo splenectomy for hemolytic anemia, malignancy, or liver transplantation at any age; (3) children who undergo splenectomy before age 5 years; and (4) persons of any age during the initial years after splenectomy. There is no consensus as to when penicillin prophylaxis should be discontinued.[60] It is important to recognize that patients receiving penicillin prophylaxis are at continued risk for fulminant infection and, thus, require the same careful and urgent evaluation for febrile illness.

Renal Disease

Children with renal disease have increased risk for infection for a variety of reasons, including underlying disease, immunosuppressive therapeutic modalities, and indwelling intravascular and peritoneal dialysis catheters.[76] Children with nephrotic syndrome and accompanying hypogammaglobulinemia have increased risk for infection with encapsulated organisms, particularly *S. pneumoniae,* which require preformed IgG for efficient opsonization. In addition, gram-negative organisms, including *N. meningitidis* and *Salmonella* spp., as well as gut flora (*E. coli, Klebsiella* spp., and *Enterobacter* spp.), account for one half of infections in this population.[77] Such patients require careful evaluation and empiric therapy effective against bowel flora as well as the encapsulated pathogens associated with BSI in patients with immunoglobulin deficiency. Patients with nephrotic syndrome also have an apparently higher frequency of urinary tract infections.[78–80]

Children with nephrotic syndrome as well as other patients with chronic renal disease should be immunized with routine pediatric vaccines, including PCV13, plus PPSV23.[46,76] Antibody levels in these patients are lower than in healthy children, but geometric mean antibody titers generally reach a protective range after immunization.[81] Duration of antibody protection may be reduced.[82] Higher doses of hepatitis B vaccine have proved more immunogenic than routine doses in children with renal failure.[83] The benefit of prophylactic penicillin in children with nephrotic syndrome is unclear because the risk for selection of multidrug-resistant organisms is of concern. Some clinicians use prophylactic penicillin in children with nephrotic syndrome who are younger than 2 or 3 years of age and have had an episode of *S. pneumoniae* bacteremia.

Patients with end-stage renal disease who are undergoing ambulatory peritoneal dialysis or hemodialysis have additional risk for infection. Patients receiving chronic ambulatory peritoneal dialysis commonly experience low-grade peritonitis, which often is due to catheter-related coagulase-negative staphylococci (CoNS). Gram-negative organisms or fungi from the bowel (e.g., *Candida* spp.) can contaminate peritoneal fluid and cause frank peritonitis. The repeated use of vancomycin in these patients may predispose to multidrug-resistant pathogens, such as vancomycin-resistant enterococci (VRE). Linezolid currently is considered the drug of choice for VRE infections in adults and often in children.[84,85] The creation of arteriovenous shunts for hemodialysis also can lead to infection, usually due to CoNS but also to *S. aureus* or other nosocomial pathogens.

Children with nephrotic syndrome who are being treated with corticosteroids (>2 mg/kg or >20 mg/day of prednisone) are at significant risk for severe varicella infection. A study of varicella vaccination in 20 children with corticosteroid-sensitive nephrotic syndrome found that antivaricella antibodies remained high 2 years after vaccination, with only 3 subjects becoming mildly infected.[86] The use of varicella-zoster immune globulin after known exposures in susceptible nephrotic children is recommended, and some clinicians also treat exposed patients with acyclovir pre-emptively, although the oral dosages used may not achieve sufficient levels to be effective.

Ascites

Patients with ascites due to either hepatic or renal dysfunction have increased risk for infection, particularly primary (spontaneous) peritonitis. Historically, these infections often were due to pneumococci or group A *Streptococcus*. Although pneumococcal peritonitis remains a major problem in children with nephrotic syndrome, children with ascites of hepatic origin also have increased risk for peritonitis due to gram-negative bacteria. The close association of primary peritonitis and ascites due to hepatic disease suggests that the compromised reticuloendothelial function of the liver associated with cirrhosis and portal hypertension allows organisms, which normally would be cleared, to contaminate hepatic lymph and pass into the peritoneal fluid. Because the liver is an important site for the clearance of bacteria from the bloodstream, significant compromise of this function leads to peritoneal infection, bloodstream infection, or both.[87,88] Experimental data suggest that bacteria also can traverse the intestinal wall to seed the peritoneal cavity. Of note, the composition of ascitic fluid contributes significantly to the development of clinically significant peritonitis; low levels of complement and immunoglobulins permit bacterial proliferation.

Although peritoneal fluid cultures are positive in most patients with ascites and peritonitis, culture techniques inadequate for recovery of anaerobic organisms may explain some negative culture results.[89] Choice of therapy is informed by peritoneal fluid Gram stain and culture as well as blood culture results. A third-generation cephalosporin such as cefotaxime may be useful for activity against possible aerobic and facultative bowel flora and *S. pneumoniae.* In children repeatedly exposed to the healthcare environment who have received multiple courses of antibiotics, the use of a carbapenem, for activity against *Pseudomonas aeruginosa,* multidrug-resistant Enterobacteriaceae (*Enterobacter, Citrobacter, Serratia, Klebsiella* spp.), and anaerobic bacteria, may be warranted initially. In adults with uncomplicated spontaneous bacterial peritonitis, a therapeutic course of a fluoroquinolone orally often is used.[87] In adults with cirrhosis, prophylactic use of a fluoroquinolone decreases the number of episodes of primary peritonitis, although it also raises the risk for selecting multidrug-resistant pathogens and *Clostridium difficile*.[90]

Iron Overload States

Patients with increased availability of free iron are at greater risk for serious infection due to *Yersinia enterocolítica*[91] and, less commonly, *Listeria monocytogenes, Vibrio vulnificus,* and *Klebsiella* spp.[92–96] Children at risk include those with (1) β-thalassemia who require chronic transfusions and iron-aluminum chelation therapy with desferoxamine[97]; (2) hemolysis due to glucose-6-phosphate dehydrogenase deficiency and other conditions[98]; (3) idiopathic hemochromatosis; and (4) chronic kidney disease managed with chronic transfusions and chelation. The use of erythropoietin in chronic anemia should decrease the use of transfusion and incidence of these infections.

Many in vitro studies demonstrate the importance of iron-scavenging systems in the virulence of bacteria and parasites as well as of free iron-depleting defense mechanisms of the host during acute infection.[94,96] As a means of innate defense, humans have evolved numerous methods of limiting availability of extracellular iron for potential pathogens. Bacteria have, in turn, evolved means to subvert innate defenses and gain access to iron. For example, uropathogenic *E. coli* have been studied extensively for their ability to produce multiple siderophores that bind iron in iron-poor conditions, which are imperative for virulence in the urinary tract.[99,100] In addition to scavenging iron from the host, *Vibrio* spp. are able to access iron by degrading host heme-containing compounds through proteolytic enzymes.[101] The importance of iron and its role in infection continues to be an active and productive area of research.[96,102,103]

Most patients with iron overload syndromes have other deficiencies in immune function due to reticuloendothelial blockade and functional asplenia. However, increased free iron itself predisposes to *Yersinia* spp. infections and has been reported even as a complication of acute iron ingestion.[104] In addition, a high rate of gram-negative BSI has been associated with the intramuscular injection of iron-dextran in neonates.[105] Acidosis, particularly diabetic ketoacidosis, leads to a greater availability of iron through a number of mechanisms and has been associated with zygomycosis in patients with acidosis.[106]

Etiologic Agents and Pathogenesis

Y. enterocolitica has been associated with septicemia, mesenteric lymphadenitis, liver and splenic abscesses, and an acute appendicitis-like syndrome in patients with thalassemia and hemochromatosis.[97,107] Organisms can be found in blood, stool, and lymph nodes. *V. vulnificus* can cause severe and often fatal BSI in these patients and also has been reported in necrotizing fasciitis in a child with congenital spherocytosis.[108] Infections caused by *L. monocytogenes, Salmonella* spp., *Klebsiella* spp., and zygomycetes are reported in patients who are treated with desferoxamine for iron overload associated with chronic transfusion.[93]

Yersinia spp., like other bacteria and fungi, require iron for growth. Unlike most other organisms, however, *Yersinia* spp. and the zygomycetes are able to use iron complexed with the siderophore desferoxamine and thrive under conditions of increased iron.[104] Several studies have demonstrated diminished host immune function (decreased phagocytic function, impaired T-lymphocyte responsiveness) in the presence of elevated serum iron levels.[109] Thus both host and bacterial factors contribute to the greater susceptibility to infection.

Clinical Manifestations and Management

The most common presentation of *Y. enterocolitica* infection in patients with thalassemia consists of fever, chills, and gastrointestinal complaints ranging from bloody diarrhea to frank peritonitis. Findings suggestive of acute appendicitis are associated with recovery of *Y. enterocolitica* from mesenteric lymph nodes. Normal hosts generally limit the organism to the intestinal mucosa, and extraintestinal infection is uncommon.

Early recognition and specific antibiotic treatment are important. Iron chelation therapy with desferoxamine should be temporarily discontinued in infected patients. Almost all *Y. enterocolitica* isolates are susceptible to trimethoprim-sulfamethoxazole, aminoglycosides, fluoroquinolones, and certain third-generation cephalosporins (cefotaxime and ceftriaxone).[110] Parenteral therapy with cefotaxime or ceftriaxone is appropriate for febrile, ill patients without focal signs of infection.

Ciliary Dysfunction

Primary ciliary dyskinesia (PCD) is an autosomal recessive disease with an incidence of approximately 1 in 15,000 to 30,000 births. At least 21 distinct ultrastructural abnormalities of cilia have been associated with the immotile cilia syndrome.[111] Approximately one half of patients with immotile cilia syndrome have situs inversus, which may be associated with Kartagener syndrome, dextrocardia, asplenia, or polysplenia. Lack of normal mucociliary clearance in the respiratory tract leads to a higher incidence of local infection. Patients with ciliary dysfunction have respiratory symptoms in the first month of life and often are colonized with *H. influenzae.*[112]

Recurrent mucopurulent rhinitis, otitis media, and bronchitis lead to bronchiectasis in as many as 85% of PCD patients. Risk for invasive infection is not increased (unless there is an associated splenic abnormality), and pulmonary function usually is preserved until late in the course of disease. Longitudinal studies suggest that patients diagnosed early in life who are treated aggressively for infection have significantly better pulmonary function than those who are not treated for infection.[113] Bronchiectasis is the most significant complication, but young infants with PCD have frequent acute otitis media, sometimes leading to hearing impairment.[114] The most common infecting organisms associated with bronchiectasis in primary ciliary dyskinesia are nontypable *H. influenzae* (47%), *S. pneumoniae* (32%), and *P. aeruginosa* (16%).[115] In upper airway infections, typical agents of acute otitis media and sinusitis are common.

Bronchodilator therapy may be useful in some patients. Antimicrobial therapy is aimed at treating existent infection and decreasing inflammation. Chest physiotherapy aids in clearance of secretions and prevention of atelectasis. Unlike cystic fibrosis (CF), ciliary dysfunction does not reduce life expectancy significantly.

Cystic Fibrosis

CF is the most common lethal genetic disease of white people. It is caused by mutations in the CF transmembrane regulator (CFTR), an adenosine triphosphate−dependent chloride channel primarily expressed in the lung and exocrine glands.[116] Patients have chronic pulmonary infection with airway inflammation and poor growth secondary to pancreatic exocrine insufficiency and malabsorption. Sinusitis secondary to abnormal secretions and nasal polyps, as well as pancreatic endocrine insufficiency, can cause significant morbidity. Aggressive medical management of the pulmonary and gastrointestinal manifestations of CF has more than doubled the life expectancy of affected patients from a median of 14 years in 1969 to a median of 40.7 years in 2013.[117,118]

Etiologic Agents

The spectrum of bacterial pathogens colonizing and infecting the lungs of patients with CF is relatively limited (Table 106.1). *S. aureus* (both methicillin-sensitive and methicillin-resistant *S. aureus*), *P. aeruginosa, and H. influenzae* (mostly nontypable) are the most commonly isolated bacterial pathogens,[119,120] and several studies demonstrate bacterial lung infections within the first 3 years of life.[121,122] *P. aeruginosa* is considered the predominant pathogen in

CF and is seen in 45% to 62% of pediatric patients.[123] Although infection with both nonmucoid and mucoid phenotypes of *P. aeruginosa* is associated with a more rapid decline in lung function, mucoid isolates signal chronic infection and are very difficult to eradicate.[124,125] Methicillin-resistant *S. aureus* also is associated with functional decline, increased number of exacerbations, and mortality in recent experience.[126–128] Later in the course of disease, multidrug-resistant gram-negative organisms such as *Burkholderia cepacia* complex, *Stenotrophomonas maltophilia,* and *Achromobacter xylosoxidans* are isolated. In recent years, the prevalence of these organisms has increased.[129,130] *B. cepacia* complex organisms, particularly *B. cenocepacia* (genomovar III) and *B. multivorans* (genomovar II), have been associated with both fulminant pulmonary infection and chronic colonization.[131] The clinical significance of *S. maltophilia* and *A. xylosoxidans* is less well characterized; however, emerging data suggest that chronic infection with *S. maltophilia* is not associated with decreasing lung function.[132–134]

TABLE 106.1

Age-Related Appearance of Pathogens in Cystic Fibrosis

Patient Age	Pathogens
Early infancy	*Staphylococcus aureus*
Early childhood	*Haemophilus influenzae*
Adolescence	*Pseudomonas aeruginosa*
Late in disease	*Burkholderia cepacia* complex *Stenotrophomonas maltophilia* *Achromobacter xylosoxidans* *Aspergillus fumigatus*

Fungi such as *Aspergillus* and *Fusarium* also cause disease in patients with CF. *A. fumigatus* can manifest as allergic bronchopulmonary aspergillosis,[135] invasive dissemination (possibly related to corticosteroid use),[136] and pulmonary or invasive disease, especially after lung transplantation.[137] In a multicenter study, nontuberculous mycobacteria were isolated from sputum in up to 13% of patients with CF—more commonly in older patients, those with a higher 1-second forced expiratory volume, those with lower body mass, and those with *S. aureus,* but not *P. aeruginosa,* isolated from sputum.[138] The effect of nontuberculous mycobacteria appears to be species driven, and *Mycobacterium* *abscessus* is associated with more rapid decline in lung function.[139,140] Whether other species of mycobacteria affect pulmonary decline remains unclear.[138] The role of infection with respiratory viruses in patients with CF has been examined in several studies. There appears to be no difference in the numbers of upper respiratory tract viral infections between children with CF and unaffected controls. However, children with cystic fibrosis have significantly more episodes of lower respiratory tract disease.[141,142] Studies support a causative role for influenza and other respiratory viruses in acute pulmonary exacerbations[143,144]; high morbidity and occasional fatality during acute influenza infection are recognized. During infancy, respiratory syncytial virus may be an important cause of early pulmonary morbidity, requiring hospitalization.[145] Rhinovirus and influenza play larger roles in early childhood and adolescence.[146,147]

Epidemiology

The epidemiology of the acquisition of *P. aeruginosa* in CF is increasingly being examined. Most children with CF appear to have unique strains,[148,149] and these early isolates share many phenotypic characteristics with environmental isolates.[150] Studies in siblings and at summer camps identify common strains in patients with close contact; it is uncertain whether these findings result from person-to-person spread or a common environmental source. Outbreaks of multidrug-resistant *P. aeruginosa* in CF centers in Europe and Australia have identified epidemic strains that appear capable of person-to-person transmission.[151,152] In addition, emerging data suggest the potential for environmental transmission through infectious droplets.[153]

Epidemiologic studies also support the conclusion that *B. cepacia* complex can be spread from person to person. Molecular typing of *B. cepacia* complex has identified unique strains in each CF center, and studies of the epidemiology in summer camps attended by patients from different geographic areas have demonstrated cross-infection.[154] Social contact outside the hospital also has been implicated in the spread of *B. cepacia* complex.[155] Of the 9 named species in the complex, *B. cenocepacia* has specific clones, especially ET12, that most clearly have been associated with transmissibility.[156] A significant problem in understanding the epidemiology of *B. cepacia* complex is the demonstration that up to 2 years may elapse from the time of acquisition of the organism until it is detected by sputum culture.[157]

Pathogenesis
